The MILES trial supports the use of about 2 mg/day of sirolimus in patients with LAM with an FEV₁ of less than 70% predicted. Lower-dose sirolimus (approximately 1 mg/day), used frequently in Japan (primarily for financial reasons), appears to be effective as well.^{184a} A single open label trial suggests that patients with rapidly declining lung function who are referred for transplantation may also benefit.¹⁸⁵ In several case reports and one small series,¹⁸⁴ sirolimus has been reported to be effective for the treatment of chylous fluid collections and lymphangiomyomas. Although sirolimus has been successfully used to treat recurrent LAM after lung transplantation,¹⁸⁶ routine use of sirolimus as first line immunosuppression is not recommended. Use in the immediate postoperative periods is associated with bronchial anastomotic dehiscence.^{186a} High serum VEGF-D is associated with baseline markers of disease severity, including need for oxygen, bronchodilator responsiveness, and reductions in FVC and DL_{CO}, and predicts disease progression and treatment response.⁷⁵ All other things being equal, a high baseline VEGF-D may tip the balance toward treatment in a patient being considered for sirolimus therapy. Early administration of long-term, low-dose suppression with sirolimus is an appealing strategy to prevent progression of LAM, but trials to determine the safety and efficacy of this approach are needed.

Other Therapeutic Considerations

Estrogen-containing medications may have adverse effects¹¹⁵ and are contraindicated. Agents that antagonize the effects of estrogen have not been proven to be effective.

A trial of bronchodilators should be considered in patients with LAM, because up to 17% to 25% of patients with LAM have bronchodilator-responsive airflow obstruction.^{11,28} Oxygen should be administered to maintain oxyhemoglobin saturations of greater than 90% with rest, exercise, and sleep. Bone densitometry should be considered in all patients who are immobilized and/or on antiestrogen therapies, and appropriate therapy instituted for osteoporotic patients. Proper attention should be paid to cardiovascular health following natural or induced menopause. Pulmonary rehabilitation seems to be particularly rewarding in this young, motivated population with obstructive lung disease, but studies to assess the effect of this intervention on exercise tolerance, conditioning, and quality of life have not been done.

GENERAL RECOMMENDATIONS—SCREENING

Sporadic LAM

Primary spontaneous pneumothorax, the most common cause of pneumothorax in young adults, happens primarily in smokers. Hagaman and colleagues¹⁸⁷ estimated that 5% of 24- to 52-year-old nonsmoking women who present with a sentinel pneumothorax have LAM and argue that HRCT screening of women in this demographic is cost effective, to the extent that it facilitates early pleurodesis that prevents recurrences.¹⁸⁷ We recommend screening in this population.

Tuberous Sclerosis–Associated LAM

HRCT screening of women with TSC identifies cystic changes in about 20% of subjects younger than 30 years old and 80% of subjects older than 40 years old.²³ The *Tuberous Sclerosis Alliance* (TSA)^{188,189} and the *European Respiratory Society* (ERS)¹⁴⁷ recommend a screening chest CT after age 18. For patients without pulmonary symptoms, the ERS recommends repeating the chest CT screen at age 30, while the TSA recommends repeat screening every 5 to 10 years. Once cysts are detected, the pace of TSC-LAM progression should be determined via HRCT testing every 2 to 3 years accompanied by annual pulmonary function and 6-minute walk testing, at least until trends are established.^{188,189} The percentage of women with TSC and cystic change on CT who become symptomatic due to LAM is generally thought to be small, probably less than 10%, but 6 of 48 (12.5%) patients with TSC-LAM in the Cudziolo study eventually succumbed to their lung disease.²³ Although cystic changes are found in approximately 10% of adult men with TSC,^{190,191} symptomatic LAM in males is very rare,¹⁸ and screening is not recommended.

The diagnosis and management issues that should be addressed in patients with LAM are outlined in [Table 69-2](#).

PREGNANCY

Patients should be advised that pregnancy has been reported to result in exacerbations of LAM in some cases.¹¹⁶⁻¹²⁰ However, risk associated with pregnancy in LAM has not been rigorously studied and decisions regarding the advisability of pregnancy should be made on an individual basis.

Table 69-2 Recommended Interventions, Studies and Immunizations in Patients with LAM**INTERVENTIONS/RECOMMENDATIONS**

Stop smoking
 Stop all estrogen-containing medications
 Counsel regarding pregnancy and air travel
 Inform patient of symptoms/management of pneumothorax, chylothorax
 Consider bronchodilator therapy
 Consider oxygen therapy
 Refer large angiomyolipomas (>4 cm in diameter) for possible embolization
 Refer for transplant evaluation for FEV₁ < 30%, disabling dyspnea, or profound hypoxia

STUDIES

High-resolution CT of the chest
 Pulmonary function testing (every 6 to 12 months)
 Serum levels of alpha₁-antitrypsin level, SS-A, SS-B, VEGF-D
 Abdominal CT, MRI, or ultrasound for angiomyolipoma (every 6 to 12 months)
 Rule out TSC with head CT or MRI, dermatologic, and ophthalmologic examinations
 Resting, nocturnal, exercise oximetry; 6-minute walk test
 Bone densitometry
 Consider transbronchial biopsy

INDICATIONS FOR LUNG BIOPSY

Cystic pulmonary change without corroborating features of known TSC or angiomyolipomata. In smokers, lung biopsy may be required to distinguish LAM from emphysema and Langerhans cell histiocytosis.

IMMUNIZATIONS

Flu shot and Pneumovax

CT, computed tomography; FEV₁, forced expiratory volume in 1 second; LAM, lymphangioleiomyomatosis; MRI, magnetic resonance imaging; SS-A, Sjögren syndrome antibody A; SS-B, Sjögren syndrome antibody B; TSC, tuberous sclerosis complex; VEGF-D, vascular endothelial growth factor D.

Women in whom LAM is diagnosed during pregnancy have high rates of pneumothorax, miscarriage, and premature birth.¹²¹ In a survey of 318 patients who indicated on their LAM Foundation intake forms that they had had at least one pregnancy, 163 patients responded to a second survey focusing on lung collapse.¹⁶² A total of 38 patients reported such an event, consistent with an incidence of pneumothorax in pregnancy of at least 10% (38 of 318). In a third of patients, the pneumothorax during pregnancy led to the diagnosis of LAM. Pneumothoraces were almost twice as frequent on the right as on the left, and four women presented with bilateral spontaneous pneumothorax. Most pneumothoraces took place during the second and third trimesters. This study and others^{14,108} suggest that pregnancy is associated with pleural complications in patients with LAM. Unfortunately, the more pressing question of whether pregnancy accelerates the decline in lung function in LAM may never be fully addressed, because so few women with a known LAM diagnosis choose to become pregnant and patients in whom LAM is diagnosed during pregnancy rarely have baseline pulmonary function tests available.

AIR TRAVEL

Whether patients with LAM are at increased risk for pneumothorax during air travel is controversial. Pollock-BarZiv

and coworkers¹⁹² found that 35% of patients with LAM had been advised by their physician to avoid air travel because of the theoretical risk for lung cyst rupture associated with atmospheric pressure changes during flight. In a survey of 276 patients who answered an LAM Foundation questionnaire, there were eight cases of radiographically documented pneumothorax associated with 454 flights. In five cases, however, symptoms that were consistent with pneumothorax may have been present before boarding. Other symptoms and signs, including anxiety (22%), chest pain (12%), shortness of breath (14%), cyanosis (2%), and hemoptysis (0.4%), were noted in 10% to 20% of flights. The conclusion from the study was that, although there were adverse events during flight in patients with LAM, air travel is well tolerated by most patients with LAM. A recent study of 281 patients with LAM who had routine chest radiograph after traveling to the National Institutes of Health identified seven with acute pneumothorax. There was no difference in the incidence of pneumothorax in patients who traveled by ground versus air. The conclusion was that pneumothorax with air travel was related to the high incidence of pneumothorax in the disease rather than the air travel itself.¹⁹³

In advising patients with LAM about air travel, it is reasonable to consider several factors, including a history of frequent or recent pneumothoraces, and the overall extent of cardiopulmonary impairment. Patients with poor cardiopulmonary reserve may tolerate even small pneumothoraces poorly. It is prudent for patients with LAM to seek medical evaluation including a chest radiograph before boarding a plane if pleuritic chest pain or unexplained shortness of breath is present. Hypoxemia during flight presents independent risks. Patients should consult with their physicians regarding recommendations for on-board oxygen use. In most cases, however, air travel in patients with LAM should not be restricted.

PLEURAL DISEASE

Pneumothoraces in patients with LAM tend to recur, especially after conservative management such as observation, aspiration, or simple tube thoracostomy. Over 65% of patients with LAM develop pneumothorax during the course of their illness, averaging 3.5 pneumothoraces per affected patient over a lifetime.¹⁰⁹ Risk of pneumothorax appears to correlate with the size of cysts.¹⁹⁴ The LAM Foundation Pleural Consensus Group advocated for the use of a pleural symphysis procedure with the first pneumothorax, given the greater than 70% chance of recurrence.¹⁰⁹ Chemical sclerosis, mechanical abrasion, talc poudrage, and pleurectomy have been effective in patients with LAM. However, for reasons that are not well explained, failure rates after pleurodesis are surprisingly high, higher than in any other chronic lung disease.

Chyle does not generally cause pleural inflammation or fibrosis, and small stable chylous effusions rarely require intervention once the diagnosis of LAM is made. Shortness of breath may mandate drainage, however, in some cases repeatedly. Pleural symphysis may be required to prevent nutritional and lymphocyte deficiencies that can result from repeated taps or persistent drainage. Chemical

pleurodesis is generally an effective therapy for chylothorax, as is mechanical abrasion and talc poudrage.¹⁹⁵

PULMONARY TRANSPLANTATION

Urban and associates¹⁴ reported the outcome of transplant in 13 patients (associated with renal transplant in 1). The mean interval between time of onset of LAM and transplant was 7.8 ± 5.2 years (range, 2.1 to 16.8 years). Mean FEV₁ before transplant was 0.57 ± 0.15 L. Boehler and colleagues¹⁹⁶ conducted a retrospective survey on 34 patients with LAM who had undergone lung transplant. The actuarial survival after 2 years was 58%, which is similar to other lung disease categories. The incidence of perioperative bleeding appeared to be higher, especially in patients with extensive pleural adhesions related to prior pleural procedures, as were complications of pneumothorax and postoperative chylothorax. The United Network of Organ Sharing recorded 126 transplants for LAM from 1989 through 2007, including 77 double-lung transplants and 49 single-lung transplants. The 1-, 3-, and 5-year survival rates for single-lung transplants were 87%, 73%, and 61%; and for double-lung transplants were 92%, 83%, and 77%, respectively. These survival rates are equal to or better than those for other disease groups transplanted in the same time frame. There have been four case reports of recurrence of LAM in the donor allograft.^{58-60,197} The recurrences did not appear to contribute to death in any of these patients and, at the present time, the risk of recurrence should not be considered in judging the candidacy of patients for transplant. More than half of patients with LAM who have undergone lung transplantation have had a prior history of unilateral or bilateral pleural fusion procedures and, although postoperative bleeding risk is increased, the operative mortality and long-term survival do not appear to be adversely affected.^{109,196}

As with other obstructive lung diseases, referral for lung transplantation should be considered when the FEV₁ falls to less than 30% of the predicted value. Some patients who fail to meet this criterion may qualify based on other factors that profoundly affect quality of life, such as disabling dyspnea or problems maintaining oxygen saturation despite high levels of supplemental oxygen. Although the question of single- versus double-lung transplantation has not been directly studied in LAM, double-lung transplantation produces better functional outcomes in other types of obstructive lung disease.¹⁹⁸ However, double-lung transplantation is not always feasible owing to the limited availability of organs and the urgency of the procedure in some patients.

ANGIOMYOLIPOMAS

Renal AMLs may require embolization or cauterization for control of bleeding, a complication that is thought to be more common when the diameter of the tumor exceeds 4 cm.¹⁹⁹ Others contend that the extent of aneurysmal change determines bleeding risk. Serial abdominal imaging should be performed to assess AML size at 6- to 12-month intervals, at least until trends in growth are clear. Nephron-sparing partial resections may be considered for very large tumors.²⁰⁰ Nephrectomy is sometimes required for tumors

with intravascular extension or other reasons, but is rarely the approach of choice for AMLs that can be managed by less invasive means. Everolimus has recently been approved by the U.S. Food and Drug Administration for the treatment of AMLs.²⁰¹

PROGRESSION AND PROGNOSIS

Progressive airflow obstruction typically develops in patients with LAM. In a cohort of patients in the United Kingdom, 10 years after symptom onset, 55% of 77 patients were breathless when walking on flat ground and 10% were housebound.²⁰² The average annual rate of decline in FEV₁ and DL_{CO} in 275 patients studied in a single laboratory at the NHLBI was 75 ± 9 mL and 0.69 ± 0.07 mL/min/mm Hg, respectively.¹⁷⁹ In other series from Europe, the rate of decline in FEV₁ was considerably higher, estimated at approximately 100 to 120 mL/yr.^{14,203,204} In the MILES trial, patients in the placebo group lost 134 mL/yr. There was some evidence in these studies that rate of decline in lung function correlates with initial DL_{CO}, with menopausal status, and with progesterone treatment. Indeed, in the placebo cohort from the MILES trial, the rate of decline in premenopausal patients was fivefold higher than the rate in postmenopausal patients (200 mL/yr vs. 40 mL/yr, respectively).¹⁸² In patients with mild disease, the development of pneumothorax appears to correlate with a faster rate of decline in FEV₁.¹⁹⁴ A positive bronchodilator response, which was associated with a lower FEV₁, was found to be a predictor of more rapid rate of decline in FEV₁ over time.¹² High baseline VEGF-D also correlates with disease progression and treatment response.⁷⁵

Survival estimates vary widely, appear to be dependent on mode of presentation or ascertainment, and have generally trended upward over the past few decades, probably due to earlier recognition through more widespread use of CT scanning. The data from early, large case series indicate that 38% to 78% of patients are alive at 8.5 years from the time of disease onset.^{8,9} Urban and associates¹⁴ reported a 91% probability of survival at 8.5 years, 79% at 10 years, and 71% at 15 years. For Japanese patients who presented with pneumothorax as the sentinel event, Hayashida and colleagues¹³ reported that 5-, 10-, and 15-year survival probabilities were 95%, 89%, and 89%, whereas for those who presented with dyspnea, survival rates were only 85%, 60%, and 47%. Matsui and coworkers²⁰⁵ found that the actuarial survival rate, based on time from lung biopsy to death or transplant, was 85% and 71% after 5 and 10 years, respectively. These investigators also developed a lung histology scoring system based on semiquantitative analyses of smooth muscle cell infiltration and cystic change, which correlated with survival. Other negative prognostic indicators that have been reported include a reduced FEV₁/FVC, increased total lung capacity, and a predominantly cystic, rather than smooth muscle hyperplastic, histology.⁹ There are no prognostic data available for TSC-LAM, but the survival of patients identified through screening is almost certainly more favorable than that of patients who present with dyspnea.^{20,22} In a population-based cohort ascertained by surveying patients registered with the LAM Foundation, the median survival was 29 years.²⁰⁶

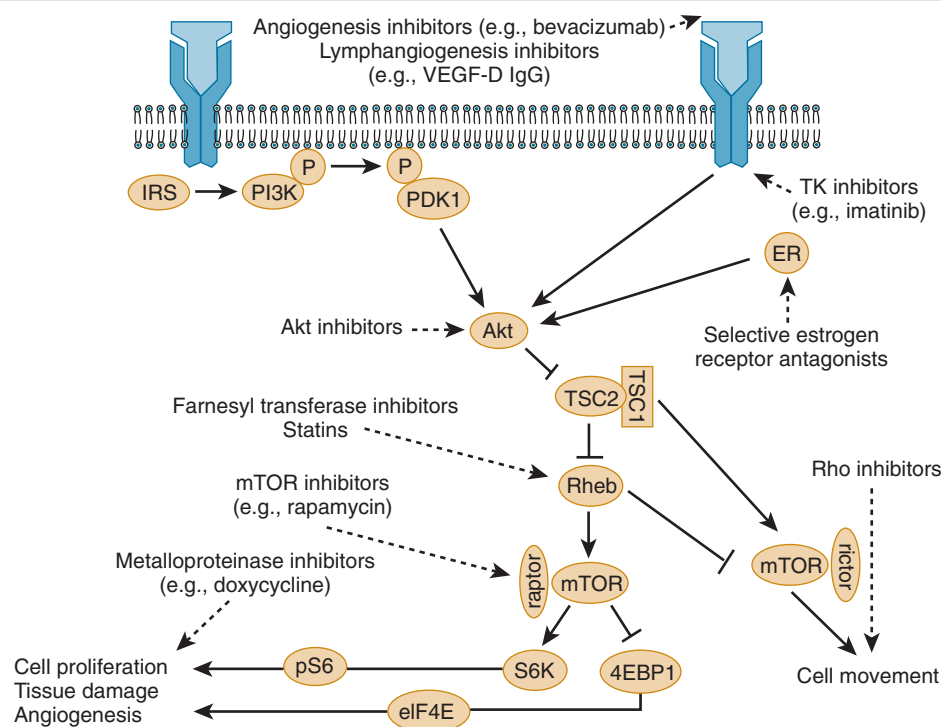

Figure 69-12 Future therapeutic targets for LAM. Knowledge of the signaling pathways that are dysregulated in patients with LAM has revealed a number of promising molecular targets for intervention. The constitutive activation of mTOR drives the inappropriate phosphorylation of S6 (pS6) when the *TSC1* or *TSC2* gene is missing or defective, as is seen in patients with LAM. pS6 (and eIF4E) drives protein translation and inappropriate cellular proliferation, but also feeds back to inhibit the activation of immunoreactive secretin (IRS) and the downstream effector Akt. This feedback loop control can be defeated by the activation of Akt through other routes, such as the platelet-derived growth factor (PDGF) and estrogen receptor pathways (which may partly explain the gender restriction in LAM). In this regard, tyrosine kinase (TK) inhibitors such as imatinib and selective estrogen antagonists may have special utility in LAM to block alternative activation of Akt. mTOR inhibitors such as sirolimus and everolimus block mTOR signaling, and statins and farnesyl transferase inhibitors block Rheb translocation to the membrane by inhibiting the lipid modification of the protein. Patients with LAM express elevated levels of the lymphangiogenic growth factor, vascular endothelial growth factor D (VEGF-D), which is currently being studied as a target in metastatic malignancy trials. Angiogenesis inhibitors such as bevacizumab and anti-VEGF-D or VEGFR-3 antibody may block blood and lymphatic vessel recruitment required for tumor maintenance, respectively, and metalloproteinase inhibitors such as doxycycline may block lung matrix degradation that plays a role in tumor implantation, spread, and tissue destruction. Cell migration, infiltration, and metastasis are controlled by a rapamycin-insensitive mTOR pathway, but may be susceptible to inhibition by rho kinase inhibitors.

FUTURE CLINICAL TRIALS IN LYMPHANGIOLEIOMYOMATOSIS

Progress in the understanding of the genetic and molecular basis of LAM has suggested a number of potential candidate therapies beyond allosteric mTOR inhibitors that may be appropriate for single agent- or combination therapy-based testing in clinical trials (Fig. 69-12). These include PI3K kinase pathway inhibitors, mTOR kinase inhibitors, Rheb and Rho inhibitors (e.g., farnesyltransferase inhibitors and statins), estrogen antagonists (e.g., gonadotropin-releasing hormone agonists), selective estrogen response modifiers, selective estrogen receptor down-regulators (e.g., Faslodex), prolactin inhibitors, aromatase inhibitors (e.g., letrozole), tyrosine kinase inhibitors (e.g., imatinib mesylate, nintedanib), metalloproteinase inhibitors (e.g., doxycycline, marimastat, batimastat), angiogenesis inhibitors (e.g., bevacizumab), and lymphangiogenesis inhibitors (e.g., anti-VEGF-D antibody, VEGFR3 antibody, pazopanib). Many of these drugs have been approved by the U.S. Food and Drug Administration or are in development for other indications.

Key Points

- *Lymphangioleiomyomatosis* (LAM) is a progressive cystic lung disease that is strikingly more prevalent in women and that most commonly presents with dyspnea on exertion and/or pneumothorax, and less commonly with chylothorax, hemoptysis, or incidentally discovered abdominal masses or pulmonary cysts.
- LAM is a metastasizing neoplasm, arising from an unknown source, associated with infiltration of lung with benign appearing smooth muscle cells and cystic parenchymal destruction.
- The diagnosis of LAM can be established on clinical grounds, using consensus guidelines and the diagnostic biomarker, serum VEGF-D, but may require transbronchial biopsy, cytologic evaluation of chylous fluid, thin needle aspirates from abdominal lesions, or, less commonly, surgical tissue confirmation.
- LAM is associated with tuberous sclerosis mutations that activate mTOR and promote growth and lymphangiogenesis, whether the mutations are in the germline in the heritable genetic disease tuberous sclerosis

or caused by somatic (non-germline) mutations in the sporadic form of the disease.

- Sirolimus is an effective treatment for LAM that should be considered in patients with abnormal lung function, rapid decline in FEV₁ or DL_{CO}, recurrence after lung transplant, or chylous complications.
- The clinical course of LAM is highly variable, but is generally slowly progressive, with 10-year survival of approximately 80% to 90% and a median survival after the onset of symptoms approaching 30 years.

eFIGURE IMAGE GALLERY

eFigure 69-1 Angiomyolipomas in LAM. **A** and **B**, Axial contrast-enhanced chest CT through the upper abdomen shows bilateral renal enlargement (left kidney outlined in black in **B**). Numerous areas of fat density (*arrowheads*, **A** and **B**) representing angiomyolipomas are present. Hepatic angiomyolipomas (arrow, **A**) are also evident. **C**, Axial chest CT displayed in lung windows shows numerous bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, which is typical of LAM. (Courtesy Michael Gotway, MD.)

eFigure 69-2 Lymphangiomyomas in LAM. Axial chest CT through the upper thorax (**A**) and axial chest CT through the pelvis (**B**) show circumscribed, faintly septated, low attenuation structures (*arrows*) representing lymphangiomyomas. **C**, Axial chest CT displayed in lung windows shows numerous bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, typical of LAM. (Courtesy Diego Ruiz, MD, Palo Alto Medical Clinic.)

eFigure 69-3 Relatively unremarkable chest radiographic appearance in LAM. **A**, Frontal chest radiograph in a patient with LAM shows relatively few abnormalities, with no findings specifically suggesting the diagnosis of LAM. Nonspecific mild right perihilar linear and reticular opacities are present. **B** through **D**, Axial chest CT displayed in lung windows shows bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, typical of LAM. The presence of comparatively fewer and smaller cysts in this patient likely contributes to the understated nature of the appearance on the chest radiograph (compare to [eFigs. 69-4, 69-5A, and 69-6A](#)). (Courtesy Michael Gotway, MD.)

eFigure 69-4 LAM—linear/reticular appearance on chest radiograph. Frontal chest radiograph in a patient with LAM shows diffuse, bilateral, symmetric linear and reticular opacities suggesting a disorder infiltrating the pulmonary interstitium. The appearance of interstitial lung disease on chest radiograph in patients with LAM may result from superimposition of the walls of the cysts characteristic of this disorder, in addition to actual interstitial space expansion resulting from lymphatic dilation and diffuse nodular proliferation of type II cells. (Courtesy Michael Gotway, MD.)

eFigure 69-5 LAM—typical imaging appearance. **A**, Frontal chest radiograph in a patient with LAM shows increased lung volumes associated with bilateral linear and reticular opacities, faintly seen to represent the walls of the cysts typical of LAM. **B**, Axial chest CT shows numerous bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, typical of LAM. (Courtesy Michael Gotway, MD.)

eFigure 69-6 “Honeycomb” or “pseudofibrotic” appearance of LAM at imaging. **A**, Frontal chest radiograph shows bilateral linear and reticular opacities, somewhat resembling interstitial/fibrotic lung disease, especially in the bases. The large lung volumes, however, strongly argue against a fibrotic interstitial pneumonia. **B**, Axial chest CT displayed in lung windows shows numerous bilateral, uniform-appearing, thin-walled cysts with relatively normal-appearing intervening lung, typical of LAM. The numerous overlapping cyst walls contribute to the “interstitial” appearance on radiography. This appearance in the bases can superficially resemble fibrotic lung disease. (Courtesy Michael Gotway, MD.)

eFigure 69-7 Spontaneous pneumothorax in LAM. **A**, Frontal chest radiograph shows a basal predominant right-sided pneumothorax (arrows). **B**, Axial chest CT displayed in lung windows shows the pneumothorax (*); thin-walled left lower lobe cysts (arrowhead), typical of LAM, are present. (Courtesy Michael Gotway, MD.)

Figure 69-8 Thin-walled cystic lung disorders simulating LAM: diffuse cystic lung disease in hypersensitivity pneumonitis. A and B, Axial chest CT displayed in lung windows shows patchy areas of ground-glass opacity associated with numerous thin-walled cysts in a patient with proven hypersensitivity pneumonitis. (Images courtesy Alejandro Gómez-Gómez, Hospital Central Dr. Ignacio Morones Prieto, Facultad de Medicina, San Luis Potosí, SLP, México).

eFigure 69-9 Thin-walled cystic lung disorders simulating LAM: cystic metastatic disease. **A–C,** Axial chest CT displayed in lung windows at diagnosis shows numerous, variably sized, bilateral solid lung nodules (*arrowheads*), representing pulmonary metastatic disease from testicular carcinoma. **D–F,** Axial chest CT following therapy for metastatic testicular carcinoma shows many of the solid nodules have evolved into thin-walled cysts (*arrowheads*). While the appearance at follow-up (**D–F**) may simulate more common causes of diffuse cystic lung disease, such as LAM and lymphocytic interstitial pneumonia, the clinical context (particularly the gender in this particular circumstance) and serial evolution from nodular lung disease readily provide differentiation from typical cystic lung disorders. (Courtesy Michael Gotway, MD.)

eFigure 69-10 Thin-walled cystic lung disorders simulating LAM: cystic metastatic disease. **A** and **B**, Axial chest CT displayed in lung windows in a patient with metastatic angiosarcoma shows several thin-walled cysts, ultimately shown to reflect metastatic angiosarcoma. (Images courtesy Diego Ruiz, MD, Palo Alto Medical Clinic.)

Figure 69-11 Thin-walled cystic lung disorders simulating LAM: cystic benign metastasizing leiomyoma. A–C, Axial chest CT displayed in lung windows shows several bilateral thin-walled cysts (*arrowheads*) and solid, circumscribed nodules (*arrows*). The cysts evolved from solid nodules on serial examinations. Biopsy showed benign metastasizing leiomyoma. (Courtesy Michael Gotway, MD.)

INTRODUCTION

Pulmonary alveolar proteinosis (PAP) is a rare syndrome characterized by abnormal alveolar surfactant accumulation and hypoxemic respiratory insufficiency. It arises in a heterogeneous group of mechanistically distinct diseases usefully divided into disorders of surfactant *production* or surfactant *clearance*.¹⁻³ Disorders of production include *pulmonary surfactant metabolic dysfunction* (PSMD) disorders caused by mutations in genes encoding surfactant proteins or genes encoding proteins involved in surfactant production. Disorders in clearance can be further divided into *primary* PAP caused by disruption of *granulocyte/macrophage colony-stimulating factor* (GM-CSF) signaling and *secondary* PAP caused by another disease or condition that disrupts alveolar macrophage surfactant clearance.

Recent advances including reports of several large cohorts⁴⁻⁷ have greatly improved our understanding of PAP pathogenesis, epidemiology, clinical subtypes, prognosis, and natural history and have resulted in new methods to diagnose, evaluate, and treat patients.^{2,8} Importantly, research on this rare and fascinating syndrome has identified the critical role of GM-CSF in alveolar macrophage ontogeny, pulmonary surfactant homeostasis, alveolar structural integrity, host defense, pulmonary and systemic inflammation, and autoimmunity. Further, studies involving GM-CSF-deficient mice identified new treatment approaches for common diseases such as asthma and rheumatoid arthritis. This chapter reviews the pathogenesis, classification, epidemiology, presentation, and therapy of PAP.

PATHOGENESIS

SURFACTANT COMPOSITION AND HOMEOSTASIS

Surfactant is a complex mixture of 90% phospholipids and 10% surfactant proteins that functions at the air-liquid-alveolar wall interface to reduce surface tension, thereby preventing alveolar collapse. It is produced in type II alveolar epithelial cells, secreted into the alveolar space, and cleared by either recycling or catabolism by type II cells or uptake and catabolism by alveolar macrophages. Surfactant composition, production, and homeostasis are reviewed in Chapter 8. Studies in animals and humans in which the pathogenesis of PAP has been elucidated have identified GM-CSF as a critical regulator of surfactant homeostasis (Fig. 70-1).

GRANULOCYTE/MACROPHAGE COLONY-STIMULATING FACTOR

GM-CSF is a 23-kD cytokine that signals via cell surface receptors comprising a GM-CSF-binding, low-affinity α chain (CDw116) and a nonbinding, affinity-converting β chain (CD131).^{9,10} Although neither chain has intrinsic signaling activity,¹¹ the β chain constitutively binds *Janus kinase 2* (JAK2),¹¹ a tyrosine kinase involved in cytokine signaling. Ligand binding causes the formation of $\alpha\beta$ JAK2 multimers and activation of JAK2, resulting in phosphorylation of α ¹² and β chains, activation of other kinases,¹¹ and initiation of signaling via multiple pathways^{11,13} including the *signal transducer of activation and transcription-5* (STAT5).¹⁴

Figure 70-1 Schematic of pulmonary surfactant homeostasis within an alveolus of a healthy individual. Surfactant lipids and proteins are synthesized in type II alveolar epithelial cells and secreted into the alveolar space. Extracellular surfactant contributes to the surfactant layer present at the air-liquid interface, which plays a critical role by reducing surface tension within the alveolus. Surfactant lipids and proteins are removed from the extracellular surfactant by uptake and recycling in type II cells or by uptake and catabolism in alveolar macrophages. Granulocyte-macrophage colony-stimulating factor (GM-CSF), a critical regulator of surfactant catabolism in alveolar macrophages, functions by binding to heterologous receptors on alveolar macrophages and stimulating surfactant catabolism via the transcription factor PU.1. GM-CSF is also critical for stimulating the terminal differentiation of precursors into mature alveolar macrophages.

MURINE MODELS OF DISORDERED SURFACTANT HOMEOSTASIS

GM-CSF-deficient (*Csf2*^{KO}) mice provided the first clue to the pathogenesis of PAP. Although neither production of surfactant by type II cells nor its uptake by alveolar macrophages was altered,^{15,16} clearance of surfactant by alveolar macrophages was impaired.¹⁷ Pulmonary GM-CSF,^{18,19} acting via the transcription factor PU.1,²⁰ coordinately regulated surfactant catabolism; cell adhesion; expression of Fc receptors, mannose receptors, and other receptors; phagocytosis; bacterial killing; and Toll-like receptor-4 signaling.²⁰ GM-CSF was identified as a critical regulator of the terminal differentiation of alveolar macrophages in mice.

GM-CSF receptor β chain-deficient (*Csf2rb*^{KO}) mice develop PAP indistinguishable from that of GM-CSF-deficient mice.²¹ Because transplantation of wild-type bone marrow corrected PAP in these mice, myeloid cells, and not lung resident epithelial cells, were identified as the cellular site of pathogenesis.²² A biomarker of PAP in these mice (increased serum GM-CSF) suggested the means that led to identification of hereditary PAP caused by *CSF2RA* and *CSF2RB* mutations in children.²³⁻²⁵ Importantly, *Csf2rb*^{KO} mice and children with *CSF2RA* or *CSF2RB* mutations develop a lung disease that is identical in every respect including lung pathology (surfactant-filled alveoli, preserved architecture); cytopathology (oil red O-stained macrophages, cell debris); alveolar macrophage biomarkers (reduced messenger RNA [mRNA] for PU.1, *peroxisome proliferator-activated receptor- γ* [PPAR- γ], ABCG1); and BAL biomarkers (increased surfactant proteins/lipids, turbidity, cytokines [GM-CSF, M-CSF, MCP-1]) and clinical course (progressive surfactant accumulation). Studies in these mice have identified *pulmonary macrophage transplantation* (PMT) as a novel therapeutic approach for hereditary PAP.²⁶

Mice deficient in ABCG1, a transmembrane protein mediating cellular cholesterol efflux, accumulate cholesterol in alveolar macrophages and type II cells and develop pulmonary lipidosis, indicating ABCG1 may be important in surfactant homeostasis.²⁷ Importantly, ABCG1 expression is decreased in alveolar macrophages from GM-CSF-deficient mice, patients with autoimmune PAP,²⁸ GM-CSF receptor-deficient mice, and patients with hereditary PAP (unpublished data). Conditional disruption of PPAR- γ (a known transcriptional regulator of ABCG1) specifically in alveolar macrophages also disrupts surfactant clearance.²⁹

Together, murine studies suggest the pathogenesis of primary PAP, both autoimmune and hereditary, may involve disruption of a pathway including GM-CSF, PU.1, PPAR- γ , and ABCG1 that is critical for surfactant clearance by alveolar macrophages.

In secondary PAP, several models have shed light on the pathogenesis. For example, reduction of alveolar macrophage numbers by chemical depletion increases surfactant pool size³⁰ and inhalation of respirable silica results in alveolar proteinosis.³¹

In addition to these models of surfactant clearance, murine models of abnormal surfactant production called PSMD disorders develop lung diseases faithfully recapitulating their respective human diseases. They are clinically, histologically, and biochemically distinct from PAP in GM-CSF-deficient mice and have improved the understanding of surfactant homeostasis. For example, SP-B-deficient mice develop respiratory failure at birth. Studies in these mice showed that SP-B is critical in the post-translational processing of SP-C, organization of surfactant phospholipids in lamellar bodies, formation of tubular myelin in alveoli, generation of surfactant films capable of reducing surface tension, and lung function during the early postnatal period.³²⁻³⁴ ABCA3-deficient mice develop respiratory failure at birth,³⁵ and studies in these mice established ABCA3 as critical to lamellar body formation and pulmonary surfactant biogenesis.³⁶

Other murine models have been shown to develop PAP and are providing insights to surfactant homeostasis including murine models of severe combined immunodeficiency,³⁷ pulmonary overexpression of *interleukin* (IL)-4³⁸ or IL-13,³⁹ and SP-D-deficiency.⁴⁰

ROLE OF GM-CSF AUTOANTIBODIES IN PRIMARY PAP

In 1999, Nakata's group first identified neutralizing GM-CSF autoantibodies in the BAL fluid and serum of idiopathic, now called *autoimmune*, PAP patients.^{41,42} Multiple subsequent studies confirmed that high levels of GM-CSF autoantibodies are associated with idiopathic PAP but not with secondary PAP, other lung diseases, PSMD disorders, or healthy individuals (Fig. 70-2).^{1-3,43,44} In one study, the concentration of GM-CSF autoantibodies in 158 idiopathic PAP patients was 113 ± 7 $\mu\text{g/mL}$,^{1,43} while levels were less than 1 $\mu\text{g/mL}$ in patients with secondary PAP, PSMD disorders, or other lung diseases.¹ GM-CSF autoantibodies are composed of IgG, predominantly of the IgG1 and IgG2 subclasses; are highly specific for GM-CSF; have a high binding affinity (20 ± 7.5 pM); and are capable of neutralizing GM-CSF at levels up to many thousands times higher than

Figure 70-2 Serum antibodies to GM-CSF are elevated in autoimmune pulmonary alveolar proteinosis (PAP). Serum GM-CSF autoantibody levels in individuals with autoimmune PAP ($n = 223$), secondary PAP ($n = 33$), pulmonary surfactant metabolic dysfunction ($n = 5$), other lung diseases ($n = 24$), and in healthy controls ($n = 13$). The detection limit of the assay was $0.5 \mu\text{g/mL}$ of serum. (Some of these data were reported in Inoue Y, Trapnell BC, Tazawa R, et al: Characteristics of a large cohort of autoimmune pulmonary alveolar proteinosis patients in Japan. *Am J Respir Crit Care Med* 177:752–762, 2008.)

the physiologic concentrations of GM-CSF in vivo.^{41,43,45} Notwithstanding these important observations, GM-CSF autoantibodies have been reported at low frequency in healthy people and in patients with autoimmune diseases without evidence of PAP; in addition, GM-CSF comprises the dominant anti-cytokine activity in pharmaceutical immunoglobulin prepared from healthy individuals.^{46,47} In a more recent study utilizing multiple detection methods, GM-CSF autoantibodies were demonstrated in all of 72 healthy individuals with no prior exposure to exogenously administered GM-CSF, albeit at low levels (median [interquartile range] = 1.04 [0.63 to 1.7] $\mu\text{g/mL}$ serum).⁴⁵ Another confusing observation was that in patients with PAP, serum GM-CSF autoantibodies did not correlate with disease severity.⁴⁴

To prove that GM-CSF autoantibodies were critical to the pathogenesis of idiopathic PAP and not a related but unimportant epiphenomenon, GM-CSF autoantibodies from these patients were isolated in pure form (i.e., a single band on SDS gels) and used to immunize healthy nonhuman primates. Results demonstrated unequivocally that GM-CSF autoantibodies reproduced the cardinal molecular and cellular features of PAP, including surfactant-filled alveoli with preserved wall architecture, foamy alveolar macrophages, alveolar macrophage biomarkers (reduced PU.1, PPAR- γ , and ABCG1 mRNA), and BAL biomarkers (increased SP-D and turbidity).^{48,49} Evaluation of GM-CSF autoantibodies isolated from the immunized primates or directly from patients has similar bioactivity.⁴⁸ Together with the clinical studies in humans, these data provided strong evidence that GM-CSF autoantibodies were in fact the pathogenic driver in idiopathic PAP, which is now recognized as *autoimmune PAP*.⁴⁸ Neutrophils from the immunized primates also had impaired phagocytosis similar to defects reported in these patients, in GM-CSF deficient mice, and in normal human neutrophils incubated with purified GM-CSF autoantibodies in vitro.⁵⁰ Using the CD11b stimulation index assay (see later), GM-CSF signaling in immunized primates was found to decrease inversely with GM-CSF autoantibody concentration at values below 5 mcg/mL and was zero at higher values, thus defining the critical threshold concentration

needed to block GM-CSF signaling.⁴⁹ In a translational study using this assay, a similar relationship and threshold were observed in humans.⁴³ Thus seemingly discrepant observations (i.e., the critical role of GM-CSF autoantibodies in PAP pathogenesis and the lack of correlation between their concentration and disease severity) were reconciled by the hypothesis that a critical threshold level of GM-CSF autoantibodies was needed to reduce GM-CSF bioactivity sufficiently to impair surfactant clearance.⁴⁷

GM-CSF autoantibodies are polyclonal and directed at epitopes throughout the GM-CSF molecule.⁴³ Evaluation of 19 monoclonal autoantibodies from 6 patients demonstrated that they use multiple immunoglobulin V genes and targeted at least four non-overlapping epitopes on GM-CSF, suggesting that GM-CSF is driving the autoantibodies and not a B-cell epitope on a pathogen cross-reacting with GM-CSF.⁵¹

The observations that GM-CSF stimulation of neutrophil functions is impaired in autoimmune PAP and GM-CSF deficient mice provides a further explanation for the increased infection risk in PAP caused by disruption of GM-CSF signaling. Further, the inverse correlation between GM-CSF autoantibody levels and neutrophil function (phagocytosis) in healthy people suggests a potential physiologic role for these autoantibodies, such as scavenging free GM-CSF, which can function as a proinflammatory cytokine. Supporting this concept, using methods capable of detecting GM-CSF, whether bound by GM-CSF autoantibody or not, serum GM-CSF concentrations in healthy people ($3048 \pm 484 \text{ pg/mL}$ serum, $n = 11$) are much higher than previously reported, and more than 99% is bound to GM-CSF autoantibodies both in healthy individuals and in PAP patients.⁴⁵

GENETIC FACTORS

A series of reports have now established hereditary PAP as a newly described genetic disease caused by genetic mutations in *CSF2RA* or *CSF2RB*, which encode GM-CSF receptor α or β chains, respectively (Fig. 70-3).^{23-25,52,53} In some cases, the genes have been cloned, the defects reproduced in vitro, the signaling abnormalities studied in detail,²³⁻²⁵ and the results used to develop several novel biomarker-based diagnostic tests (see later). One particularly useful test, serum GM-CSF, was used to identify a number of patients with hereditary PAP due to mutations in the GM-CSF receptors and is capable of identifying patients with defects in either chain of the receptor.^{23-25,54} Of importance to the pathogenesis of PAP, in families with two siblings carrying the same function-impairing GM-CSF receptor gene mutation, the older sibling had minimal disease while the younger sibling had more extensive disease, suggesting another factor besides loss of GM-CSF signaling is important in determining disease severity in hereditary PAP.²⁴ Several genetic factors associated with hematologic disease and secondary PAP have been identified including mutations in the gene encoding the transcription factor GATA2, as well as in GMCSF receptor chain genes.^{54a,79}

Mutations in three genes encoding surfactant proteins, *SFTPB*, *SFTPC*, and *ABCA3*, disrupt surfactant production and function and cause respiratory disease in neonates,

Figure 70-3 Genetic mutations in *CSF2RA* and *CSF2RB* and corresponding GM-CSF receptor α and β chain abnormalities associated with the development of hereditary pulmonary alveolar proteinosis. For each gene, a schematic of the normal protein is shown above to indicate regions corresponding to the signal peptide, extracellular domain, transmembrane spanning domain, and intracellular domain. Shown below each normal protein are the abnormal proteins caused by genetic mutations (indicated) known to cause hereditary PAP. (Some data are from Suzuki T, Sakagami T, Young LR, et al: Hereditary pulmonary alveolar proteinosis: pathogenesis, presentation, diagnosis, and therapy. *Am J Res Crit Care Med* 182:1292–1304, 2010.)

children, and older individuals.⁵⁵⁻⁵⁸ See Chapter 8 for additional information on pulmonary surfactant. SP-B and SP-C are hydrophobic peptides that reside within the surfactant phospholipid layer, which functions to reduce surface tension at the alveolar air/liquid interface,³⁴ whereas ABCA3 likely transports lipids, including phosphatidylcholine, cholesterol, sphingomyelin, and phosphatidylglycerol, into lamellar bodies in alveolar type II cells, where the surfactant complex is assembled, processed, and stored.

SFTPB is a small gene (9.7 kb) encoding a 79-amino acid, hydrophobic protein. Infants homozygous for recessive loss-of-function mutations in *SFTPB* develop respiratory failure and die shortly after birth.^{59,60} In contrast, individuals heterozygous for SP-B deficiency alleles have normal lung function.⁶¹ More than 30 mutations have been identified to date in fewer than 100 infants with SP-B deficiency.^{58,62} Two thirds have an insertional frameshift mutation caused by the replacement of a single nucleotide by three nucleotides at codon 121 (designated 121ins2). Among infants with SP-B deficiency, approximately 60% are homozygous for the 121ins2 mutation, 25% are heterozygous for this and another function-altering allele, and 15% have other mutations. SP-B deficiency is associated with the aberrant processing and secretion of an immature SP-C peptide, which may contribute to the respiratory failure associated with hereditary SP-B deficiency.⁶³

SFTPC is a small gene (3 kb) encoding a 35-amino acid hydrophobic protein. Known mutations in *SFTPC* are expressed in a dominant fashion and are associated with interstitial lung disease in neonates, children, and adults.^{58,64-67} Twenty-five percent of individuals with SP-C-associated lung disease have a point mutation in *SFTPC* causing the substitution of threonine for isoleucine at codon

73 (I73T).⁶⁵ Immunohistochemical analysis of lung tissue from an infant with the I73T mutation demonstrated normal staining patterns for pro-SP-B, SP-B, and pro-SP-C. Although infants with this mutation can present with respiratory distress syndrome, most children with the mutation become symptomatic with interstitial lung disease beyond the newborn period.^{65,68}

ABCA3 is a large gene (80 kb) encoding a 1704-amino acid protein. Autosomal recessive mutations in *ABCA3* can result in fatal surfactant deficiency in neonates^{69,70} and chronic respiratory insufficiency in older children.⁷¹ Function-altering mutations in *ABCA3* result in surfactant that is deficient in phosphatidylcholine and has decreased function, suggesting that *ABCA3* has an important role in pulmonary surfactant phospholipid homeostasis.⁷² A relatively common missense point mutation in *ABCA3* causing the substitution of a valine for glutamic acid at codon 292 (E292V) is associated with chronic interstitial lung disease in older children who are heterozygous for this and a different function-altering mutation on the other *ABCA3* allele.⁷¹

NKX2.1 is essential for expression of SP-B, SP-C, and *ABCA3*. Haploinsufficiency of the gene encoding for the transcription factor *NKX2.1* (also known as thyroid transcription factor 1 or TTF1) causes a complex phenotype in neonates that includes, albeit variably, hypothyroidism, brain abnormalities, and acute and chronic lung disease.^{73,74}

Although the lung diseases associated with mutations in *SP-B*, *SP-C*, *ABCA3*, and *NKX2.1* disrupt surfactant homeostasis, cause varying degrees of surfactant accumulation (i.e., PAP), and are often cited as hereditary forms of PAP in the medical literature, they are distinguished from disorders of surfactant clearance by their surfactant dysfunction (i.e., functionally abnormal surfactant), histopathologic

abnormalities (gross parenchymal derangement and interstitial disease), and clinical course. Consequently, the term *pulmonary surfactant metabolic dysfunction* (PSMD) disorders has been proposed for this group of genetic disorders.

DISEASE ASSOCIATIONS

PAP has been reported in association with various medical conditions believed to cause the disorder, resulting in use of the term *secondary* PAP.^{1,2} Systemic disorders associated with secondary PAP include malignant and other hematologic diseases, nonhematologic malignancies, immune deficiency syndromes, chronic inflammatory syndromes, and chronic infections (Table 70-1). In the past, chronic myelogenous leukemia and myelodysplastic syndrome were the most frequently reported hematologic disorders associated with PAP.^{2,75-77} In one single-institution study, PAP was reported in 5.3% of patients with hematologic malignancies and in 8.8% of those who were neutropenic.⁷⁶ Of possible pathogenic significance, 9 of 10 patients in one study were neutropenic when PAP developed and, in most, PAP recovered spontaneously after bone marrow engraftment. In another, PAP developed during a period of neutropenia that resolved after treatment with granulocyte colony-stimulating factor.⁷⁸ In a third report, PAP developed in three patients with acute myeloid leukemia with GM-CSF receptor abnormalities, including reduced levels of the β chain (three of three) and undetectable α chain (two of three).⁷⁹ PAP has been found in about 10% of patients with lysinuric protein intolerance, an ultra-rare inherited

disorder caused by defective cationic amino acid transport.^{80,81} Secondary PAP has been reported in association with various forms of immunodeficiency, including thymic alymphoplasia,⁸² immunoglobulin A deficiency,⁸³ solid organ transplantation,⁸⁴ and acquired immunodeficiency syndrome.⁸⁵

Although the mechanism(s) responsible for secondary PAP are poorly studied, two common themes have emerged when considered in the context of the critical role of alveolar macrophages in surfactant homeostasis. Conditions reducing either the numbers or functions of alveolar macrophages would be expected to reduce the capacity of resident alveolar macrophages to clear surfactant from the lung surface.

ENVIRONMENTAL FACTORS

PAP has been associated with inhalation exposure to environmental agents including cigarette smoke, a wide variety of organic and inorganic dusts, fumes, and gases (Table 70-2). Epidemiologic studies (see later) document that PAP is more common in smokers. Five of the 27 original patients reported by Rosen and colleagues⁸⁶ had been exposed to wood dust. Most reports implicating other environmental exposures are single cases or small retrospective series and, in general, have not established a causal relationship between the exposure and development of PAP. One early report on 138 PAP patients found that half had significant exposure to dust and fumes, of which the most common exposure was to inhaled silica, noted in 10 individuals.⁸⁷ With the advent of occupational protective equipment in the workplace, this form of “acute silicoproteinosis”^{88,89} is rare. Other case reports document the association of PAP with exposure to aluminum dust,⁹⁰ cellulose fibers, cement dust, titanium dioxide,^{91,92} indium-tin oxide,⁹³ and nitrogen dioxide. The link between silica and PAP is supported by studies in rats demonstrating that inhalation of silica particles disrupts surfactant homeostasis, resulting in increased

surfactant accumulation.^{31,94} In five separate large series of patients with PAP,^{2,4-7} a history of dust exposure, when data were available, was present in 26% to 54% of patients.⁷ Further research is necessary to determine what role environmental inhalation exposure plays in the pathogenesis of PAP.

MECHANISMS OF DISRUPTION OF SURFACTANT HOMEOSTASIS

In mice, a series of observations has established GM-CSF as a critical regulator of pulmonary surfactant homeostasis, including the following: (1) surfactant homeostasis requires the presence of GM-CSF in the lung, and PAP develops in the absence of either pulmonary GM-CSF or its receptor; (2) surfactant accumulation in GM-CSF-deficient mice is caused by decreased catabolism by alveolar macrophages and not by increased production; (3) pulmonary GM-CSF is required for normal expression of transcription factor PU.1 in alveolar macrophages, and enforced (i.e., retroviral-mediated) expression of PU.1 restores surfactant catabolism in alveolar macrophages from GM-CSF knockout mice; and (4) surfactant homeostasis can be restored in GM-CSF receptor β -deficient mice by transplantation of bone marrow from a wild-type mouse.

Primary PAP (Autoimmune and Hereditary)

In humans, studies elucidating the pathogenesis of autoimmune and hereditary PAP show that GM-CSF is also critical for surfactant homeostasis in humans. Supportive data include (1) GM-CSF autoantibodies (a) are present at high levels only in autoimmune PAP, (b) can be isolated in pure form, (c) cause PAP after injection into healthy primates, and (d) retain biologic activity after injection^{48,49}; (2) GM-CSF autoantibodies neutralize vastly higher amounts of GM-CSF than is present physiologically⁴³; (3) in PAP patients, PU.1 expression is reduced in alveolar macrophages and increased by GM-CSF therapy⁹⁵; (4) disruption of GM-CSF signaling by *CSF2RA* or *CSF2RB* mutations causes lung disease histopathology indistinguishable from that of GM-CSF knockout mice and autoimmune PAP in humans^{23-25,52,53}; (5) reduced expression of GM-CSF receptor β on leukocytes is associated with PAP in children and with development of PAP in leukemia patients⁷⁹; and (6) disorders that transiently reduce numbers and/or functions of alveolar macrophages are temporally related to the development and resolution of secondary PAP in humans.⁷⁸

Available evidence suggests that GM-CSF regulates myeloid cell functions similarly in humans and mice. GM-CSF knockout mice and autoimmune PAP patients have remarkable similarity in (1) pulmonary histopathologic appearance of the lung; (2) cytologic and ultrastructural appearance of alveolar macrophages; (3) elevation of certain cytokines (monocyte chemotactic protein-1, macrophage colony-stimulating factor); (4) the pattern of differential impairment of various neutrophil functions; and (5) the increased incidence of pulmonary and extrathoracic secondary infections.

The pathogenic mechanism in primary PAP is (1) disruption of GM-CSF signaling to alveolar macrophages, either by the absence of GM-CSF (observed in mice, but not yet in humans); (2) disruption of GM-CSF signaling by mutations

in the GM-CSF receptor proteins (in mice and humans), or (3) disruption of GM-CSF by an autoimmune attack that neutralizes GM-CSF, eliminating GM-CSF bioactivity and myeloid cell stimulation in vivo (in humans and nonhuman primates). GM-CSF, via PU.1, regulates catabolism of surfactant in alveolar macrophages (in mice and possibly humans). Surfactant accumulation in PAP is due to reduced clearance by alveolar macrophages, but the precise mechanism is unknown. Because pulmonary surfactant is internalized into macrophages by endocytosis and catabolized in phagolysosomes, it is possible that interruption of GM-CSF signaling blocks the translocation of endocytosed surfactant to lysosomes. Such a mechanism has been demonstrated for adenovirus internalized by macrophages from GM-CSF-deficient mice, in which PU.1 redirects adenovirus-containing endosomes to lysosomes for destruction. Alternatively, GM-CSF deficiency may result in a key enzyme deficiency. Potentially supporting this possibility are data related to the *peroxisome proliferator-activated receptor- γ* (PPAR- γ), a ligand-activated transcription factor regulating genes involved in lipid metabolism and other pathways.⁹⁶ PPAR- γ messenger RNA and protein are expressed in alveolar macrophages in healthy individuals, decreased in PAP patients, and increased by GM-CSF therapy of PAP patients.⁹⁵ CD36, a lipid scavenger receptor regulated by PPAR- γ , is regulated in a similar pattern. However, PPAR- γ deficiency has been noted in several other disorders, including sarcoidosis, acute respiratory distress syndrome, and asthma, where there have been reports of surfactant abnormalities.⁹⁷ Further studies are required to determine the mechanism by which interruption of GM-CSF signaling leads to reduced catabolism of surfactant by alveolar macrophages.

Secondary PAP

The mechanisms involved in secondary PAP, although less well supported by experimental data, likely involve reduced numbers or functions of alveolar macrophages. This would decrease the surfactant clearance capacity of resident alveolar macrophages and is supported by data demonstrating a temporal relationship of the onset and resolution of PAP with the suppression and restoration of myeloid cells in hematologic disorders. Other secondary mechanisms of PAP—for example, due to inhalation of toxic fumes and dusts—are less clear. Presumably, they would involve a reduction in the ability of alveolar macrophages to clear surfactant. However, because overexpression of certain cytokines (IL-4, IL-13) or decreased expression of some *surfactant proteins* (SP-D) also increases surfactant production in mice, other potential mechanisms appear possible.

Pulmonary Surfactant Metabolic Dysfunction

Mechanisms of PSMD involve mutations in genes of the surfactant synthetic pathway, including *SFTPB*, *SFTPC*, *ABCA3*, *NKX2.1*, and likely others, and result in the production of biochemically and functionally abnormal surfactant. These disorders have a lung histopathology and clinical course that is markedly different from PAP caused by interruption of GM-CSF signaling. Further, the pathophysiology arises from surfactant deficiency rather than surfactant excess as in PAP. Thus it may be appropriate to consider these disorders as distinct from PAP and not part of a spectrum of PAP.

NOMENCLATURE AND CLASSIFICATION

Since PAP was first described as a lung disease “of the filling of the alveoli by a PAS-positive proteinaceous material, rich in lipid,”⁸⁶ it has become recognized as a syndrome caused by distinct diseases¹ and is reported in the medical literature using numerous terms, resulting in a nomenclature that is redundant, inconsistent, and confusing. Terms have been based on the biochemical characteristics of the accumulated material (e.g., alveolar proteinosis, phospholipidosis); pathogenesis (e.g., silicoproteinosis, idiopathic); disease category (e.g., primary vs. secondary); and timing of symptom onset (e.g., congenital, acquired) and are redundant (e.g., idiopathic PAP, acquired PAP, pulmonary alveolar lipoproteinosis, phospholipoproteinosis, alveolar lipoproteinosis, alveolar proteinosis, alveolar phospholipidosis, and alveolar lipophosphoproteinosis). Confusion arises from use of the same term for different diseases. For example, the term *congenital PAP* has been used for the disease caused by mutations in *SFTPB*, which is uniformly fatal at birth and caused by surfactant deficiency, and also for the disease caused by GM-CSF receptor deficiency that presents in children, is caused by surfactant accumulation, and can be treated successfully.

The foregoing discussion underscores the need for a classification and nomenclature that will facilitate clear communication about disorders of homeostasis necessary for clinical training, disease management, and research. On the basis of initial discussions of a global task force assembled by the Rare Lung Diseases Consortium, a simplified classified scheme is proposed (Table 70-3).

Disorders of surfactant homeostasis are separated into disorders of reduced *clearance* (PAP) or abnormal *production* (PSMD). PAP is further subdivided into primary and secondary categories, depending on whether it is due to a primary disturbance of GM-CSF signaling or secondary to another disease, respectively. *Primary PAP* is composed of several specific disease mechanisms: an autoimmune disease

caused by GM-CSF autoantibodies (autoimmune PAP) or a genetic disease caused by mutations in *CSF2RA* or *CSF2RB*. A third disease, caused by GM-CSF deficiency, exists in mice and is predicted but not yet observed in humans. *Secondary PAP* arises in association with several disease categories, including hematologic disorders, malignancy, immune deficiency syndromes, chronic inflammatory disorders, and chronic infections (see Table 70-1), as well as in association with certain inhalation exposures, especially silica (sandblasters) (see Table 70-2). PSMD disorders are those arising from mutations in genes of the surfactant synthesis pathway, including *SFTPB*, *SFTPC*, *ABCA3*, *NKX2.1*, and likely others that have yet to be identified.⁵⁶ These disorders are included in a new classification of interstitial lung disease in young children.⁹⁸

The plethora of terms used to report on the PAP syndrome are not recommended for continued use and should be replaced with the term *pulmonary alveolar proteinosis*. Terms referring to clinical presentation (i.e., acquired PAP, congenital PAP) should not be used when the underlying disease is known. For example, “SP-B deficiency” is far more informative than “congenital PAP” and more consistent with its pathogenesis as a disorder of surfactant deficiency (PSMD) rather than excessive surfactant accumulation (PAP). When the cause is unknown, the term *unclassified PAP* is preferred over “idiopathic PAP” because the latter is currently understood to be the disorder caused by high levels of GM-CSF autoantibodies.

EPIDEMIOLOGY

Disorders of surfactant homeostasis are found in worldwide distribution but are rare. Since the initial description of PAP, more than 1000 cases of primary or secondary PAP^{2,4,23,86,99} and substantially fewer cases of PSMD^{55-58,64,65,69,71,100-102} have been reported in the medical literature (Table 70-4). A comprehensive meta-analysis of 410 separate cases of PAP representing all clinical subtypes found that patients were more likely to be male (male-to-female ratio = 2.65:1.0) and that males predominated among smokers (male-to-female ratio = 2.78:1.0) but not among nonsmokers (male-to-female ratio = 0.69:1.0).² These results suggested that the high proportion of males among PAP patients may be explained by their higher frequency of tobacco use. This study also found the median age at diagnosis to be 39 years (39 in men and 35 in women).

Autoimmune PAP has been studied in several ways to establish its epidemiology. A large national, multicenter, registry-based study of PAP was recently conducted in Japan and identified 223 patients with autoimmune PAP.⁴ This study reported a male predominance (male-to-female ratio = 2.1:1.0) and found that males predominated among smokers (male-to-female ratio = 9.3:1.0) but not among nonsmokers (male-to-female ratio = 0.6:1.0).⁴ The median age at the time of diagnosis was 53 years (52 in men and 55 in women). The prevalence was similar in nine nonoverlapping geographic regions encompassing the entirety of Japan, and the case rate correlated closely with the regional population size. This result suggests the absence of an effect of climate or geography on the prevalence. Further

supporting this, autoimmune PAP is seen in a worldwide distribution. An intensive screening within the Niigata prefecture in Japan (population 2.41 million) estimated the incidence and prevalence of autoimmune PAP to be 0.49 ± 0.13 and 6.2 per million, respectively.⁴ This registry found that, among noncongenital cases of PAP, 89.9% of cases were autoimmune, 9.7% were secondary, and 0.4% were unclassified. In a meta-analysis of 1045 primarily adult PAP patients in five recent series,⁷ the mean age at diagnosis was similar in 4 out of 5 series (ranging from 39 to 43) and slightly older in the Japanese series (mean age of 51). In all series, males prevailed over females, with a ratio ranging from 1.3:1 to 2.6:1. The interval between onset of symptoms and diagnosis was similar (ranging from 7 to 11 months). Importantly, between 21% and 43% of PAP patients were never-smokers, indicating that PAP is not simply a smoking-related disease.

Hereditary PAP is caused by various genetic mutations in *CSF2RA* or *CSF2RB* genes (see Fig. 70-3) and usually presents in children between the ages of 1.5 and 11 years, although it has been observed to present in adults aged 29 and 35 years.^{23-25,52,53}

Secondary PAP accounts for not more than 10% of all PAP cases in adults^{2,4} and develops as a consequence of an underlying disease (see Table 70-1) or environmental exposure (see Table 70-2). Thus the prevalence of secondary PAP is estimated to be approximately 0.34 per 100,000 individuals in the general population. Historically, hematologic malignancy was the most common cause of secondary PAP, accounting for up to 5.3% of cases.⁷⁶ However, in a recent study, myelodysplastic syndrome accounted for 65% of cases.¹⁰³ Secondary PAP arises as a function of the underlying clinical disorder and, in some cases, can resolve with successful treatment of the underlying disorder.

PSMD disorders develop in individuals with mutations in the genes involved in surfactant synthesis: *SFTPB*, *SFTPC*, *ABCA3*, and *NKX2.1*, as discussed earlier. The incidence of SP-B deficiency is estimated to be approximately 1 per 1.5 million births. Among infants with respiratory distress syndrome of unknown etiology, mutations appear more commonly in *ABCA3* than in *SFTPB*.⁵⁶ The prevalence of the common disease-associated mutations in the *SFTPB* (121ins2), *SFTPC* (I73T), and *ABCA3* (E292V) genes are

not well established. However, a recent study in ethnically diverse cohorts from Missouri, Norway, South Korea, and South Africa ($n = 420$) found the population-based frequencies of these mutations to be rare ($<0.4\%$). Further, E292V was present in 3.8% of newborns with respiratory distress syndrome, suggesting it imparts an increased genetic risk for this syndrome.⁵⁵

CLINICAL PRESENTATION

Autoimmune PAP presents as progressive dyspnea of insidious onset unless secondary infection is also present, in which case fever, cough, and rarely hemoptysis may also be present. The frequency of various symptoms was recently evaluated in a large contemporaneous cohort in Japan (Table 70-5). This nonspecific presentation may lead to months or years of misdiagnosis as “asthma” or “chronic bronchitis.” The symptoms are frequently milder than expected from the radiographic findings, which should raise the suspicion of PAP. The physical examination is nonspecific and is frequently normal despite a grossly abnormal chest radiograph but may include basilar crackles. Cyanosis is seen in severe cases; hemoptysis and fever are rare. Clubbing is not a feature of autoimmune PAP or of hereditary PAP. In the Japanese national PAP registry cohort, 31% of patients with marked radiologic manifestations were asymptomatic.⁴

Hereditary PAP caused by mutations in GM-CSF receptor genes (*CSF2RA* or *B*) presents as insidious, progressive, dyspnea-like autoimmune PAP, usually in children.^{23,24,52,53} Thus, whereas this disease is newly described, rare, and necessarily less well studied, it appears similar to autoimmune PAP, except that it is a disease of children instead of adults.

Secondary PAP usually arises in an individual with an underlying systemic disorder such as a hematologic malignancy/disease.^{75,76,78,99,104,105} It can be seen in the context of neutropenia or myeloid cell dysfunction related to the underlying disorder and can resolve with successful treatment of the underlying disorder.

PSMD disorders can present as a spectrum of lung disease ranging from respiratory distress syndrome in neonates and infants to interstitial lung disease in children, adolescents, and adults, depending on the exact nature of the underlying genetic mutations. SP-B deficiency typically presents as respiratory distress immediately after birth.^{59,68,106} *ABCA3* mutations can result in fatal respiratory distress syndrome in neonates and interstitial lung disease in infants, children, and adolescents.^{69,71,102,107} SP-C mutations can present as interstitial lung disease in children and adults.^{58,64,66,67,101}

EVALUATION AND DIFFERENTIAL DIAGNOSIS

RADIOGRAPHIC APPEARANCE

The chest radiograph in autoimmune PAP and secondary PAP of hematologic origin typically reveals bilateral patchy or diffuse air-space consolidation or hazy ground-glass opacity (eFig. 70-1) similar in appearance to that of pulmonary edema but without the other radiographic signs of left heart failure.^{86,108} Other patterns can include mixed alveolar, interstitial (eFig. 70-2), or nodular opacities and asymmetrical or focal abnormalities (eFig. 70-3), but dense consolidation with air bronchograms is uncommon. Lymphadenopathy, cardiomegaly, and effusions are not features of PAP. The chest radiograph in hereditary PAP is similar but may be normal early in the clinical course or in mild cases.²³ The diagnostic value of the chest radiograph is limited by its lack of specificity.

Conventional chest *computed tomography* (CT) scans demonstrate bilateral areas of consolidation with poorly defined margins (Fig. 70-4).^{109,110} High-resolution chest CT (eFig. 70-4) is superior to both conventional CT and chest radiography in the assessment of the pattern and distribution of abnormalities and may demonstrate lesions even when the radiograph is normal. The distribution of disease is variable and may reflect heterogeneity of underlying disease causing PAP. Several features are noteworthy. Areas of *ground-glass opacification* (GGO) often have sharply defined straight and angulated margins, giving them a “geographic” appearance. The sharp margination usually reflects lobular or lobar boundaries. A pattern of fine overlapping lines forming 3- to 10-mm polygonal shapes can be seen in the majority of cases. Superimposition of these two patterns gives an appearance that has been described as “crazy paving,” which is *characteristic but not diagnostic*

Figure 70-4 CT of different forms of PAP. CT of the chest illustrating differences in the radiographic appearance of the lungs in autoimmune PAP (A), hereditary GM-CSF receptor (α chain) dysfunction (B), and secondary PAP in a child with lysinuric protein intolerance (C). Note the juxtaposition of highly abnormal secondary lobules (open arrows), adjacent to more normal-appearing secondary lobules (solid arrows). This is referred to as a “geographic” pattern and is common in autoimmune PAP. It is also seen in hereditary PAP due to GM-CSF receptor dysfunction. Opacities that are more homogeneous and less geographic are more common in secondary PAP (C).

of PAP (eFig. 70-5).¹¹¹ Notably, crazy paving can also be seen in hypersensitivity pneumonitis, *Pneumocystis jirovecii* pneumonia, minimally invasive adenocarcinoma/lepidic invasive adenocarcinoma (formerly bronchioloalveolar carcinoma), lymphangitic carcinomatosis, cardiogenic pulmonary edema/acute lung injury, and lipoid pneumonia (eFig. 70-6). One study reported that a geographic appearance with crazy paving is more commonly seen in autoimmune than secondary PAP.¹¹²

Findings on the chest radiograph and high-resolution chest CT correlate with a restrictive ventilatory defect, reduced diffusing capacity, and hypoxemia.¹¹⁰ Quantitative CT measurements of ground-glass opacities, lung weight, and gas volume may be useful in following patients with PAP.¹¹³

PULMONARY FUNCTION TESTING

The results of pulmonary function testing may be normal or, in more advanced disease, may show a restrictive ventilatory defect with mild impairment of the forced vital capacity and total lung capacity and a disproportionate, severe reduction of the diffusing capacity for carbon monoxide.^{2,4} Arterial blood gases show mild to severe hypoxemia, an increased alveolar-arterial PO₂ gradient, compensated respiratory alkalosis depending on the degree of disease progression, and absence of hypercarbia. The shunt fraction is elevated when compared with patients with other diffuse lung diseases.¹¹⁴ Six-minute walk testing typically reveals early desaturation.

BRONCHOSCOPY, BRONCHOALVEOLAR LAVAGE, AND TRANSBRONCHIAL BIOPSY

Bronchoscopic airway examination is unremarkable in PAP. In contrast, *bronchoalveolar lavage* (BAL) specimens usually reveal characteristic gross, cytopathologic, and biochemical findings highly suggestive or diagnostic of PAP. In autoimmune, hereditary, and secondary PAP but not PSMD, the BAL fluid has a “milky” or “waxy” appearance and sediment forms on standing (Fig. 70-5). Cytologic examination of periodic acid–Schiff–Papanicolaou-stained specimens reveals the BAL fluid and sediment contains granular, acellular, lipoproteinaceous material,¹¹⁵ cells, and fat globules. Strikingly, cytopsin preparations reveal alveolar macrophages engorged with intracytoplasmic lipid droplets

imparting a foamy appearance by light microscopy (Fig. 70-6). Electron microscopic examination of the sediment reveals the presence of tubular myelin, lamellar bodies, and fused membrane structures characteristic of pulmonary surfactant. The BAL cell differential in autoimmune PAP may be normal or reveal the presence of increased pulmonary lymphocytes composed of increased numbers of CD4⁺ and CD8⁺ cells.¹¹⁶ Cultures of bronchoscopic washings and BAL are important to rule out infection.

Biochemical analysis of BAL fluid reveals increased amounts of phospholipids and proteins, similar in composition to that of surfactant from healthy individuals.¹¹⁷ Surfactant proteins are variably increased in the BAL fluid in PAP.

SURGICAL LUNG BIOPSY

Because of the diagnostic accuracy of BAL, lung biopsy is generally not necessary to make the diagnosis of PAP but may be indicated when the diagnosis is in doubt or secondary PAP is suspected. Macroscopically, the cut surface of lung biopsy specimens in autoimmune and hereditary PAP reveals a geographic pattern of 2- to 3-cm grayish-yellow regions of firm consolidation that exudes fatty material (eFig. 70-7). Microscopically, alveoli and terminal airways are filled with a fine eosinophilic material that stains strongly for surfactant proteins (see Fig. 70-6). The alveolar wall and interstitial architecture are relatively well preserved, but lymphocyte infiltration and occasionally fibrosis can be seen. The vasculature appears normal. Electron microscopy, which is seldom necessary, reveals characteristic, concentrically laminated surfactant structures (lamellar body inclusions) within the granular material and in alveolar macrophages.¹¹⁸ Importantly, although a lung biopsy can establish the presence of PAP syndrome, it cannot identify the disease responsible (e.g., autoimmune or hereditary PAP, Fig. 70-6E and F, respectively), which has important implications for newer therapies.

LABORATORY STUDIES

Routine laboratory studies are usually normal in PAP. Serum lactate dehydrogenase is typically elevated in proportion to lung disease severity, although this finding is nonspecific.^{2,114} Serum levels of SP-A, SP-B, SP-D, C-reactive protein, and *Krebs von den Lungen protein-6* (KL-6), a mucin-like protein (MUC1), are increased in PAP and correlate with lung disease severity.^{4,44,119} However, all of these biomarkers can be elevated in other lung diseases.^{120,121} Thus although not useful in diagnosis, these biomarkers may be useful in monitoring disease activity in patients with PAP. For example, KL-6 has been reported to outperform arterial PO₂ and LDH in predicting disease progression and need for therapy in autoimmune PAP.¹²²

Several biomarker-based tests are effective for the diagnosis of disease-specific PAP. The most well established is the serum-based GM-CSF autoantibody ELISA test.^{1,45,50,123,124,124a} Although serum GM-CSF autoantibodies are present at low levels in healthy people,⁴⁵ a high serum level is diagnostic of autoimmune PAP. In a recent validation study (MICEPAP) conducted in the United States, Germany, Italy, and Japan, both the sensitivity and

Figure 70-5 Whole-lung lavage fluid. Saline (A) compared to the whole-lung lavage fluid from a patient with autoimmune PAP (B). The lavage fluid, which was allowed to settle overnight in the refrigerator, shows a “milky” appearance and dense sediment.

Figure 70-6 Appearance of sputum, sputum cytology, and lung histopathology in PAP due to disruption of GM-CSF signaling. **A**, Gross appearance of freshly expectorated sputum from a patient with uncomplicated autoimmune PAP. **B**, Sputum smear after staining with periodic acid–Schiff reagent. **C**, Sputum smear after staining with Papanicolaou reagent. Note the appearance of large, foamy-appearing alveolar macrophages in **B** and **C**. **D**, Alveolar macrophage stained with Oil Red O. **E**, Histopathologic appearance of an open-lung biopsy in autoimmune PAP after periodic acid–Schiff staining. Alveoli are filled with amorphous, acellular eosinophilic material and also cholesterol clefts and eosinophilic bodies. Alveolar wall architecture is well preserved. **F–J**, Histopathologic appearance of an open-lung biopsy in hereditary PAP caused by *CSF2RA* gene mutations after staining with hematoxylin and eosin (**F**), or immunostaining for SP-A (**G**), mature SP-B (**H**), pro-SP-C (**I**), or SP-D (**J**). (**F–I** from Suzuki T, Sakagami T, Rubin BK, et al: Familial pulmonary alveolar proteinosis caused by mutations in *CSF2RA*. *J Exp Med* 205:2703–2710, 2008.)

specificity of a recently improved assay were found to be 100%.¹²⁵ Furthermore, an international *monoclonal GM-CSF autoantibody reference standard* (MCRS) was developed to help standardize test results from the few laboratories that currently perform the test. When the GM-CSF autoantibodies are at levels close to the diagnostic threshold, measurement of GM-CSF signaling in whole blood is useful and can be done by measuring the ability of exogenous GM-CSF to bind GM-CSF receptors on leukocytes and stimulate an increase in cell surface CD11b (the CD11b stimulation index test)⁵⁰ or an increase in STAT5 phosphorylation (the STAT5-phosphorylation index test).¹²⁶ Both assays give similar results (a large increase in healthy people and no change in autoimmune PAP), but the latter is more robust and reliable. Measurement of the serum concentration of GM-CSF by ELISA is a useful screening

test to identify patients with hereditary PAP in whom GM-CSF signaling is disrupted not by GM-CSF autoantibodies but by GM-CSF receptor dysfunction.^{23,127} Various molecular and genetic tests are available to determine the specific abnormality in hereditary PAP and PSMD.^{24,25}

APPROACH TO DIAGNOSIS

The timely diagnosis of PAP requires a high degree of clinical suspicion, and PAP should be suspected in patients with dyspnea of insidious onset and typical chest CT findings. In previously healthy adults with these findings, an abnormal serum GM-CSF autoantibody test is usually sufficient to establish the diagnosis of autoimmune PAP.¹²⁵ An abnormal GM-CSF signaling test, either the *STAT5 phosphorylation index* (STAT5-PI) or the *CD11b stimulation index*

(CD11b-SI) test, confirms the diagnosis. Pulmonary function testing may be helpful if the disease is moderate or severe but is normal (except for DL_{CO}) in many patients.³ Although BAL cytology or a surgical or transbronchial lung biopsy can establish the presence of PAP syndrome, none can identify the underlying disease.⁹⁹ An open-lung biopsy is usually not necessary, but a biopsy may still be useful if the diagnosis is unclear or if secondary PAP is suspected to rule out disorders that have radiologic, cytologic, or pathologic features similar to PAP.

In younger patients in whom PAP is suspected, the presentation can be helpful. SP-B deficiency presents as respiratory failure at birth. ABCA3 dysfunction can present similarly or as interstitial lung disease in infants, children, and adolescents. SP-C dysfunction presents as interstitial lung disease in children and adults. Although autoimmune PAP usually presents in adults, it has been seen in children as young as 3 years and can readily be diagnosed by blood test without the need for a lung biopsy. Hereditary PAP often presents in children between the ages of 1.5 and 11 but can present as late as age 35. In hereditary PAP, the serum GM-CSF autoantibody test is normal and the GM-CSF signaling tests, STAT5-PI (CD11b-SI), and serum GM-CSF tests are abnormal.²³⁻²⁵ These blood-based tests are useful in evaluating young patients and should be employed to minimize the use of more invasive procedures.

The diagnostic workup of individuals with disorders of surfactant homeostasis, including PAP and PSMD disorders, consists of routine clinical evaluations, biomarker evaluations, and genetic tests capable of distinguishing among autoimmune PAP, secondary PAP, hereditary PAP caused by receptor dysfunction, and PSMD disorders (Fig. 70-7).

NATURAL HISTORY

No longitudinal studies of the clinical course of PAP have been reported. However, cross-sectional evaluations of PAP cohorts in Japan, China, Germany, and Italy have recently been reported (see Table 70-4).⁴⁻⁷ In Seymour and Presneill's comprehensive meta-analysis of PAP, the actuarial survival rates for 343 patients with acquired PAP were $78\% \pm 8\%$ at 2 years, $75\% \pm 8\%$ at 5 years, and $68\% \pm 9\%$ at 10 years.² More than 80% of the deaths attributable to PAP during a 5-year period took place during the first 12 months after diagnosis. This study reported that, of the 69 deaths, death was caused by respiratory failure from PAP in 47 patients (72%), uncontrolled infection in 13 (20%), and unrelated causes in 5 cases (8%). In a contemporaneous cross-sectional cohort study of 223 autoimmune PAP patients in Japan, there were no deaths over the 5-year period of the study.⁴ Autoimmune PAP follows one of three patterns: progressive deterioration, stable disease, or spontaneous resolution.² Secondary PAP may have a far worse prognosis than autoimmune PAP: A recent study of 40 individuals with secondary PAP diagnosed premortem reported a median survival of less than 20 months from diagnosis.¹⁰³

SECONDARY INFECTIONS

Multiple reports document increased infections in PAP by microbial pathogens ranging from community- and hospital-acquired organisms to *Nocardia* spp. (eFig. 70-8) or opportunistic organisms.² GM-CSF-deficient mice also have increased mortality from infection and increased susceptibility to a wide variety of microbial pathogens, including

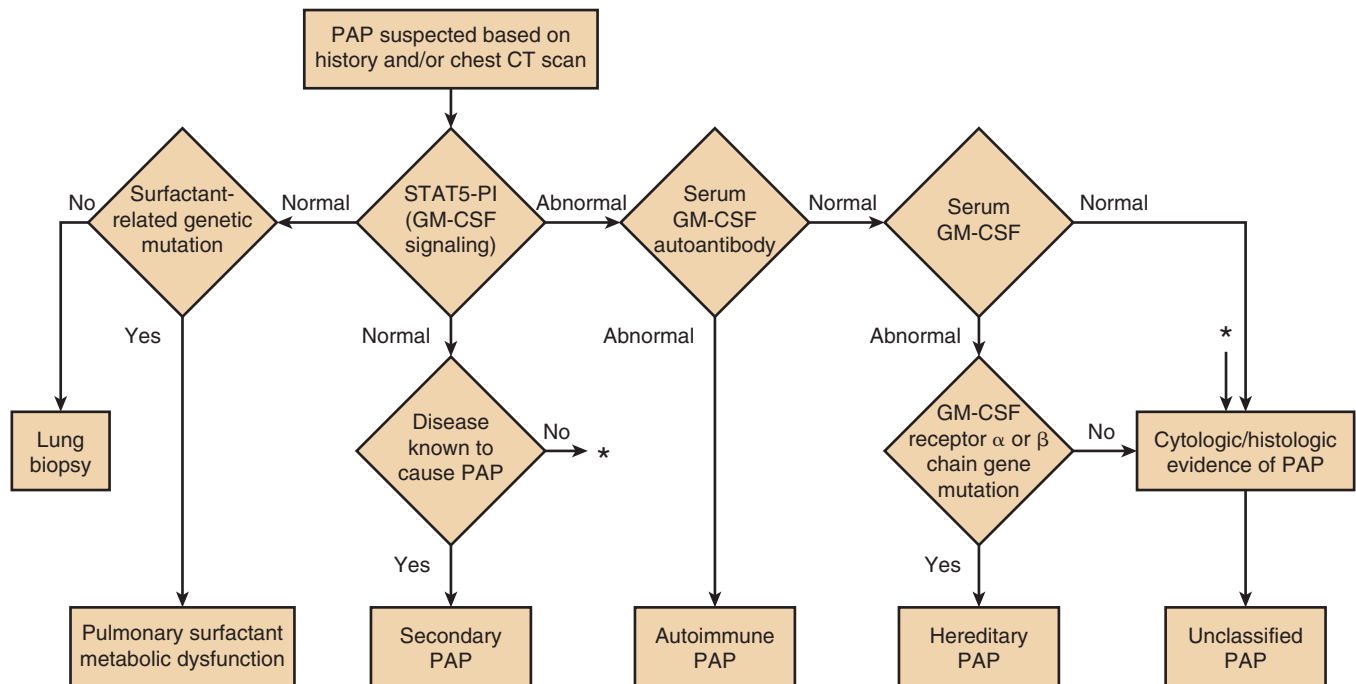

Figure 70-7 Diagnostic algorithm for evaluation for individuals with PAP syndrome. In hereditary PAP caused by mutations in GM-CSF receptor genes *CSF2RA* or *CSF2RB*, further GM-CSF signaling tests are necessary to confirm and identify the specific nature of the defect. See text for details. STAT5-PI, STAT5 phosphorylation index. *, links decision tree in algorithm.

bacteria, fungi, and mycobacteria (eFig. 70-9). Further, myeloid cells from both patients with autoimmune PAP and GM-CSF-deficient mice have defects in innate immune functions, including phagocytosis, generation of reactive oxygen species, inflammatory signaling, and bacterial killing.^{20,45,50,123,128} In both GM-CSF-deficient mice and PAP patients, infections can arise in the lungs and at extrathoracic locations, consistent with a systemic immune defect caused by disruption of GM-CSF signaling.

PULMONARY FIBROSIS

Pulmonary fibrosis has been reported in association with PAP and has been reproduced in animal models of exposure to inhaled silica.^{31,118} Further, exposure to oxygen or repeated *whole-lung lavage* (WLL) has been suggested as potentially contributing to fibrosis. However, although not adequately studied, “end-stage lung disease” or irreversible scarring of the lung is rarely associated with PAP.

SPONTANEOUS RESOLUTION

Spontaneous improvement of PAP (eFig. 70-10) was noted in Rosen’s initial report.⁸⁶ In subsequent case series, spontaneous resolution was described in 5% to 8% of patients (see Table 70-4).⁴⁻⁷

TREATMENT

Various therapeutic strategies have been proposed for PAP. WLL emerged early and served as the standard therapy for nearly 5 decades, albeit with some refinements. Novel therapeutic approaches have recently been developed based on recognition of the critical role of GM-CSF in surfactant homeostasis and of the neutralizing GM-CSF autoantibodies in PAP pathogenesis. These novel approaches include GM-CSF augmentation, plasmapheresis, and anti-B lymphocyte therapy. Each is discussed briefly as follows.

AUTOIMMUNE PAP

Whole-Lung Lavage

Originally developed by Ramirez in the early 1960s, WLL is a procedure performed under general anesthesia in which large volumes (commonly 20 to 30 L, but up to 50 L) of saline are infused sequentially into each lung to “wash out” the accumulated surfactant lipids and proteins while the other lung is mechanically ventilated.¹²⁹⁻¹³¹ A number of procedural variations have been tested (although none systematically), including the use of mechanical chest percussion, prone positioning, variation in the volume of infusate, and use of a hyperbaric chamber. Notwithstanding improvements, WLL has not been standardized with respect to the method (i.e., volume infused, use of mechanical percussion, the end point of an individual lavage procedure); indications for its use; methods for evaluating the treatment effectiveness; or timing of repeated procedures. The end point used clinically for terminating lung lavage in the operating room is a clearing of the appearance of the lavage effluent. No studies have systematically evaluated the procedure, its

utilization in clinical practice, or the efficacy or durability of clinical responses. Notwithstanding, among practitioners, it is widely believed to improve symptoms, radiographic findings, and gas exchange in PAP patients.^{132,133}

Although WLL is safe in the vast majority of individuals, complications include hypoxemia, pneumonia, sepsis, acute respiratory distress syndrome, hydrothorax, pneumothorax, and pneumomediastinum (eFig. 70-11). The procedure should not be performed in a patient with an active microbial lung infection because this can result in sepsis and shock. Bronchoscopic segmental or lobar lavage has been proposed as a safe alternative in patients in whom WLL under general anesthesia is considered risky due to severe hypoxemia.¹³⁴ Other alternatives include performance in a hyperbaric chamber¹³⁵ and use of complete cardiopulmonary bypass.¹³⁶

A comprehensive literature review identified 231 individuals for whom sufficient WLL data were available and reported that lavage was associated with increased overall 5-year survival ($94 \pm 2\%$ with lavage [$n = 146$] versus $85 \pm 5\%$ without lavage [$n = 85$]; $P = 0.04$).² This study also reported that the median number of WLL procedures performed was two and that 70% of patients underwent the procedure within 5 years of diagnosis. Among 55 individuals undergoing the procedure, the median duration of benefit was 15 months and only 20% of patients remained free of recurrence at 3 years. Among 41 patients with adequate available data, arterial PO₂ improved by 20.1 mm Hg after WLL (Table 70-6). The improvement in other pulmonary function test parameters was less impressive. More than 95% of patients respond to WLL; however, a small fraction of patients did not respond despite aggressive lavage. Improvement results from the physical removal of the accumulated surfactant and can be evident within hours of completion of therapy.

In practice, the indications for WLL therapy include dyspnea, exercise intolerance, and a desire to reduce the requirement for supplemental oxygen therapy. Reasonable indications for performing the procedure may include dyspnea limiting activities of daily living, arterial PO₂ less

Table 70-6 Therapeutic Response to Whole-Lung Lavage Therapy of Adults with PAP

Parameter	N	Mean Change ± SD	95% CI of the Mean	P Value*
Arterial PO ₂ (mm Hg)	41	20.1 ± 14.3	15.6 to 24.6	<0.0001
(A–a)PO ₂ (mm Hg)	21	–30.6 ± 18.0	–38.8 to –22.4	<0.0001
FEV ₁ (L)	33	0.26 ± 0.47	0.09 to 0.42	<0.0034
VC (L)	40	0.50 ± 0.54	0.33 to 0.67	<0.0001
DL _{CO} (mL/mm Hg per minute)	25	4.4 ± 4.5	2.6 to 6.3	<0.0001

*Value is for the comparison of paired postlavage with prelavage data for individual patients for each parameter for only those patients with available data using a two-sample t-test.

(A–a)PO₂, alveolar-arterial difference in oxygen tension; CI, confidence interval; DL_{CO}, diffusing capacity of carbon monoxide; FEV₁, forced expiratory volume in 1 second; PAP, pulmonary alveolar proteinosis; VC, vital capacity.

than 60 mm Hg while breathing room air, significant desaturation (>5%) on exercise,⁷ and a shunt fraction greater than 10% to 12%.

Granulocyte/Macrophage Colony-Stimulating Factor

GM-CSF therapy of PAP was first shown to be effective in a single patient in 1995.¹³⁷ A follow-up study in 14 autoimmune PAP patients receiving GM-CSF by subcutaneous injection in escalating doses (5 to 20 µg/kg/day) over a 3-month period reported an overall response rate of 43%.¹³⁸ A subsequent study in 21 autoimmune PAP patients receiving GM-CSF by subcutaneous administration in escalating doses (5 to 18 µg/kg/day) for 6 to 12 months reported an overall response rate of 48% as defined by a 10 mm Hg or greater improvement in room air arterial PO_2 .¹³⁹ Several case studies have reported similar findings. In aggregate, results indicate that (1) subcutaneous GM-CSF therapy of autoimmune PAP may result in objective improvement in about 50% of patients, (2) the therapeutic response is variable among patients, (3) the therapeutic response depends on the dose and duration of treatment, and (4) there is a lag of about 8 weeks before a therapeutic response is seen. These studies have not demonstrated a consistent change in the GM-CSF autoantibody level.

Aerosolized GM-CSF therapy of autoimmune PAP has been tested in small studies using daily inhaled doses of GM-CSF ranging from 125 to 500 µg per patient per day.¹⁴⁰ In one larger study in 50 autoimmune PAP patients, 35 patients with unremitting/progressive disease received aerosolized GM-CSF therapy initially at an “induction” higher dose (250 µg on days 1 to 8 of 14, ×6 cycles) followed by a lower “maintenance” (125 µg on days 1 to 4 of 14, ×6 cycles).¹⁴¹ In this study, which excluded patients who improved spontaneously during an initial observation period and thus only evaluated patients with unremitting/progressive disease, the overall response rate was 62%. Results suggested that delivery of GM-CSF by aerosol induced a higher clinical response rate than by the subcutaneous route. Furthermore, whereas both routes appeared to be safe, local site reactions and other minor problems were noted in 85% of patients receiving subcutaneous GM-CSF, while no treatment-related side effects were noted with inhaled GM-CSF. In another retrospective study of 12 individuals, administration of up to 500 µg bid every other week by aerosol resulted in complete remission in two patients and an overall response rate of 92%.^{141a} Currently, nonhuman toxicology studies of inhaled GM-CSF therapy are under way to help define the safety of this promising therapeutic approach for autoimmune PAP.

Rituximab and Other Approaches

Other therapeutic strategies aimed at reducing the level of GM-CSF autoantibodies, including plasmapheresis and B-lymphocyte depletion, have been tried in a few patients. One study evaluating a single cycle of rituximab therapy in 10 patients gave promising results,¹⁴² but further studies are necessary before any useful conclusions can be drawn about the potential utility of this theoretically attractive strategy. Lung transplantation has been performed successfully in a 41-year-old patient with PAP (probably autoimmune PAP), but the disease recurred 3 years later.¹⁴³

HEREDITARY PAP

WLL is the standard therapy for hereditary PAP caused by *CSF2RA* or *CSF2RB* mutations.^{23,24} Bone marrow transplantation has been tried without success in one child.⁵³ Recently, gene correction and pulmonary macrophage transplantation have shown promising results in a mouse model of hereditary PAP.²⁶

SECONDARY PAP

Secondary PAP, in some cases caused by hematologic disorders, can resolve with resolution of the underlying disorder. Nonresolving secondary PAP can be effectively treated with WLL. However, this has not been well studied.

PULMONARY SURFACTANT METABOLIC DYSFUNCTION DISORDERS

Therapy of these disorders depends on the disease and presentation; care is generally supportive and includes assessment of need for supplemental oxygen and nutritional support. In very young children, WLL is extremely challenging and of uncertain efficacy, and an adapted technical approach to airway management is required during lavage.¹⁴⁴ Neonates may show transient improvement with exogenous surfactant administration. Lung transplantation can be considered in cases of SP-B deficiency and in severe and progressive disease from *ABCA3* mutations.

GAPS IN KNOWLEDGE AND FUTURE DIRECTIONS

ETIOLOGY

Autoimmune PAP, the most common PAP disease, has a well-explained pathogenesis even though its etiology remains obscure. Although it has been established that GM-CSF, via PU.1, is critical for surfactant homeostasis in humans and that GM-CSF autoantibodies mediate the pathogenesis of autoimmune PAP, the precise mechanism by which loss of GM-CSF signaling reduces surfactant clearance by alveolar macrophages is unknown. The immunopathology of autoimmune PAP, while of particular interest, is largely unexplored.

In contrast, secondary PAP is less well studied in terms of pathogenesis, but in some cases the etiology (i.e., loss of alveolar macrophages in hematologic disorders and after chemotherapy) seems clear.

Hereditary PAP also has a clear etiology (i.e., genetic mutations in *CSF2RA* or *CSF2RB*). However, the pathogenesis beyond the loss of GM-CSF signaling is unclear.

PSMD disorders have a clear etiology and continue to provide important information regarding surfactant production and processing.

CLINICAL PRACTICE GUIDELINES

Standardized clinical practice guidelines for pulmonary alveolar proteinosis are necessary. WLL has been in use for

nearly 5 decades, yet no studies have prospectively evaluated the indications for, timing of, or methods to monitor outcomes of the procedure. Nor has the procedure itself been standardized with respect to volume of infusate, use of mechanical percussion, hyperbaric oxygen, position or repositioning of the patient during the procedure, or objective methods for terminating the procedure.

NOVEL THERAPEUTIC APPROACHES

Results of clinical trials suggest that inhaled GM-CSF in patients with autoimmune PAP is safe and effective. However, existing results have not defined the optimal dose, timing, or duration of administration, which could potentially improve the current response rate. Nor has the mechanism underlying the therapeutic effect been determined. It is puzzling why administration of GM-CSF to these patients does not result in any increase in GM-CSF autoantibody levels, but this appears to be the case. Further research is necessary to evaluate other therapies, including plasmapheresis, anti-B lymphocyte therapy, and combination therapies. Examples of the latter include combining WLL with aerosolized GM-CSF to improve the benefit from lavage and combining plasmapheresis and anti-B lymphocyte therapy to deplete GM-CSF autoantibodies.

Key Points

- *Pulmonary alveolar proteinosis* (PAP) constitutes a group of heterogeneous diseases and is characterized by surfactant accumulation in alveoli due to either impaired surfactant clearance by alveolar macrophages or abnormal surfactant production.
- The molecular pathogenesis is now known in most cases: mechanisms include (1) disruption of GM-CSF signaling by GM-CSF autoantibodies (autoimmune PAP, ≈85% of cases) or GM-CSF receptor mutations (hereditary PAP, ≈5% of cases), (2) disruption of alveolar macrophage numbers or functions by a separate disease (secondary PAP, ≈5% of cases), and (3) disruptions of surfactant amount or function by mutations resulting in abnormal surfactant production (pulmonary surfactant metabolic dysfunction disorders, ≈5% of cases).
- PAP can present in men, women, and children of all ethnic backgrounds and in all geographic locations and has an estimated overall prevalence of 7 to 10 per million in the general U.S. population and globally.
- The patient with PAP typically presents with progressive dyspnea of insidious onset with or without cough but, if infection is also present, may also have fever, diaphoresis, or hemoptysis.
- The natural history depends on the disease responsible. In autoimmune PAP, the clinical course varies and includes respiratory failure and death in a small fraction, slowly progressive/stable disease in most, and spontaneous improvement in 6% to 8% of patients.
- Characteristic (but nondiagnostic) chest CT findings and bronchoalveolar lavage results are used to diag-

nose PAP syndrome but cannot identify the disease causing it. However, new blood tests (including GM-CSF autoantibody level, GM-CSF signaling assays [e.g., STAT5-PI], and serum GM-CSF) currently available as clinical research tests can identify the PAP-causing disease in more than 95% of cases.

- Whole-lung lavage is the current standard therapy for autoimmune PAP, hereditary PAP, and some (myelodysplasia) but not all (silica-induced) forms of secondary PAP, but it is not useful in pulmonary surfactant metabolic dysfunction disorders. GM-CSF, particularly by inhalation, and rituximab are promising experimental therapeutic approaches under active study.

INTRODUCTION

Adverse drug reactions have been the object of intense scrutiny since the early 1990s and have been recognized as a top safety priority by health care quality improvement organizations across the United States.¹ A groundbreaking report published in 1999 by the Institute of Medicine only intensified this attention by suggesting that medical errors, including medication errors, may be responsible for 98,000 patient deaths per year in the United States.² Specifically, medication errors and preventable adverse drug events may injure 1.5 million people and cost billions of dollars annually. Up to 2% to 5% of hospitalized patients may have non-preventable adverse drug reactions.³ The classification of drug reactions includes allergic or hypersensitivity reactions, overdosage, intolerance, idiosyncratic reaction, side effects, and secondary effects.

We know relatively little about the pharmacokinetic properties of drugs in individual patients. Many drug-related injuries are not reproducible in animals and therefore cannot be studied in depth. Moreover, if a drug administered in the therapeutic dose range caused an adverse reaction in most of the patients who received it, the drug would not be usable. Indeed, only a small percentage of the population develops pulmonary toxicities to otherwise successful drugs. Nevertheless, drug-induced pulmonary diseases represent a significant problem and are likely underrecognized. It is estimated that less than 5% of all adverse drug-induced pulmonary diseases and overall less than 1% of serious and unexpected events are formally reported to the U.S. Food and Drug Administration (FDA).¹ The number of drugs associated with pulmonary toxicity is steadily increasing.⁴ By 2009, more than 350 drugs have

been identified to cause adverse pulmonary reactions. These reports are of various nature and quality, ranging from clear toxicities established in large series to isolated case reports. Some of these medications are listed in Table 71-1. To minimize mortality and significant morbidity, it is incumbent on the clinician to keep in mind at least the more common drugs that may induce pulmonary disease.⁵⁻⁸

Four mechanisms of drug injury to the lungs are recognized: (1) oxidant injury, such as during chronic nitrofurantoin ingestion; (2) direct cytotoxic effects (and these effects may be aggravated by oxidant injuries); (3) deposition of phospholipids within cells, such as those produced by cationic amphiphilic drugs such as amiodarone; and (4) immune-mediated injury through drug-induced *systemic lupus erythematosus* (SLE).^{6,9-13} Although extensive investigation has been undertaken to look for other forms of immune system–mediated injury, only the SLE induced by drugs has been proven.

CHEMOTHERAPEUTIC AGENTS

Chemotherapeutic agents are extensively used in solid and hematologic malignancies but are also increasingly employed for their immunosuppressive properties in the management of various inflammatory disorders. Because of the severity of the diseases in which they are employed, higher risks for potential adverse lung reactions are typically tolerated, and as such, pulmonary complications of chemotherapy are common in this clinical setting. It is, however, a diagnostic challenge for the clinician who must determine the responsibility of the chemotherapeutic agent, usually on the basis of a diagnosis of exclusion, and decide

whether or not to discontinue it, with the risk of depriving his or her patient of a potentially life-saving therapy.

Oncology patients are prone to a number of pulmonary complications irrespective of their chemotherapy regimen, including opportunistic infections, atypical presentations of common lung infections, radiation-induced lung injury, cardiogenic or noncardiogenic pulmonary edema, and, of course, metastatic lung involvement. The various presentations of drug-induced pulmonary disease must be rapidly differentiated from these other etiologies whose clinical presentations, including fever and diffuse radiographic abnormalities, may be extremely similar to chemotherapy-induced pulmonary reactions. As combination regimens are generally the rule, it can become difficult to incriminate one agent over the other. Chemotherapy-associated pulmonary reactions have become a major problem, particularly in relation to therapeutic regimens containing bleomycin, methotrexate, cyclophosphamide, and a host of newer agents (Table 71-2).

Table 71-2 Selected Chemotherapeutic Agents with Associated Pulmonary Toxicities

ANTIBIOTIC-DERIVED AGENTS	PODOPHYLLOTOXINS

Chloroethyl cyclohexyl nitrosourea (CCNU)	Zinostatin
Methyl-CCNU	Vinblastine

Consistent criteria for drug-induced lung disease have not been officially established. Uncertainty that a given respiratory complication is linked to a particular drug is generally present. Confirmation with rechallenge is to be avoided because it is often neither practical nor generally ethical. Hence the diagnosis of cytotoxic lung damage rests on an appropriate history of drug exposure, histologic evidence of lung injury, and the exclusion of other causes of the lung damage. There is no single diagnostic test or tissue biopsy that can definitively confirm the diagnosis of chemotherapy-associated lung disease. Thus a careful and thorough evaluation to eliminate the possibilities of other conditions producing these effects, particularly infection, is warranted. It is estimated that 10% to 20% of patients undergoing some type of chemotherapy will develop respiratory symptoms directly related to their treatment.^{8,14} Thus the clinician should maintain a high index of suspicion and carefully screen for other competing causes of pulmonary injury that may affect these immune-compromised patients.

The clinical presentation of many chemotherapy drug effects is quite similar, with the exception that some present more acutely, whereas others tend to be more insidious in their onset. In general, nonproductive cough, dyspnea, and often fever begin weeks to years after the agent is first administered. Occasionally, symptoms may present acutely, as in the case of hypersensitivity reactions or infusion reactions. Symptoms may also manifest years after discontinuation of the drug, perhaps reactivated by radiotherapy, a process called “radiation recall.” Fever is common with most chemotherapeutic drug-induced pulmonary injury, but it may not be consistently present, and chills are usually absent. Weight loss may be present. The chest radiograph in cases of chemotherapy-induced lung disease may be unremarkable for days or weeks before showing typical changes of a diffuse interstitial infiltrative pattern. Alternatively, there may be a diffuse mixed alveolar-interstitial

Figure 71-1 Cytotoxic pattern of drug-induced lung disease. A close-up chest radiograph showing an alveolar interstitial pattern that is characteristic but not diagnostic of cytotoxic lung disease.

pattern, which may occasionally be useful in recognizing early drug effects (Fig. 71-1). Auscultation of the lungs will frequently reveal crackles, which are also nonspecific. In some instances, pleural effusions may be present during adverse drug reactions, but not consistently.

Pulmonary function studies are abnormal in almost all patients with cytotoxic drug-induced lung disease when compared with pretreatment testing. The *carbon monoxide diffusing capacity* (DL_{CO}) may decrease before reduced volumes are detected. In addition, this decrease in DL_{CO} may precede the onset of symptoms and radiographic changes by days or weeks.¹⁴ In several prospective investigations, diffusing capacity has been used to detect early onset of pulmonary reactions, at which time the agents are discontinued to minimize progression into overt clinical disease.¹⁵ *Bronchoalveolar lavage* (BAL) may be another means of assessing early lung damage from these drugs; however, the results are often variable. In general, the greatest utility of BAL is to exclude infection.

ANTIBIOTIC-DERIVED AGENTS

Bleomycin

Bleomycin is an antibiotic chemotherapeutic agent that was isolated in 1966 from *Streptomyces verticillus*. Its pulmonary toxicity was recognized early and has since been one of the main factors limiting its use in the clinical

setting. The incidence of bleomycin lung toxicity ranges anywhere from 0% to 46%; pulmonary function testing and chest radiographs reveal that 20% of patients treated with bleomycin develop overt pulmonary disease, and up to 3% die from pulmonary consequences of bleomycin therapy.^{14,16}

The mechanisms by which bleomycin exerts its antineoplastic effects are diverse. Direct cytotoxic effect, prevention of neoangiogenesis by the tumor, stimulation of the production of various cytokines, and free radical generation via formation of a complex between ferrous iron and oxygen are likely the most important.¹⁷⁻²⁰ The latter effect may explain increased bleomycin toxicity with high fractions of inspired oxygen. This is often a problem during anesthesia and in the postoperative recovery period.^{21,22} This sensitivity to supplemental oxygen may persist for months and, perhaps, years after discontinuation of the drug. Perhaps one of the most consistent features of bleomycin-induced lung disease is the concept of cumulative toxicity. The incidence of pulmonary toxicity is significantly greater in those who have received a cumulative dose of greater than 450 units, with a 10% death rate in those having received a total dose greater than 550 units of bleomycin. However, doses as little as 50 units may occasionally be enough, especially when other synergic factors are present. Rapid rates of delivery by the intravenous route may also play a role, and slower infusion rates, as well as intramuscular injections, have been recommended.

Bleomycin is metabolized primarily by the kidneys. Hence renal failure predisposes to impaired metabolism of the drug and increased toxicity. It is also inactivated by an enzyme, bleomycin hydrolase, present in most tissues except for the lungs and skin. The lack of a detoxifying enzyme in the skin may explain the scleroderma-like skin changes occasionally observed with bleomycin. Radiotherapy is itself a common cause of pulmonary complications and is also thought to promote the generation of free radicals, toxic to both the tumor cells and surrounding tissues. The concomitant use of bleomycin and radiotherapy may be synergistic. Treatment with bleomycin may reactivate prior radiation-induced lung disease, a process called *radiation recall*, as mentioned earlier as an example of a delayed drug reaction. Pulmonary toxicity is also increased in patients older than 70 and in those with preexisting lung disease. There is good evidence that pediatric patients may also be at increased risk, with 70% of children treated with bleomycin for rhabdomyosarcoma developing pulmonary toxicity in one study.²³ Impaired or immature ability to process free radicals and inadequate kidney function may explain these differences. Finally, bleomycin toxicity may be synergistically increased by several other chemotherapeutic agents.

Although of uncertain value, determination of pretreatment DL_{CO} and its frequent monitoring have been suggested in an attempt to predict subsequent clinical deterioration. A progressive fall in the DL_{CO} should prompt withdrawal of further bleomycin administration.²⁴ Vital capacity and pulmonary capillary blood flow may be better predictors of lung toxicity.²⁵ In addition, the enhanced sensitivity of *computed tomography* (CT) scanning may also be useful in establishing an early diagnosis of bleomycin pneumonitis. In one series of 100 patients receiving bleomycin, chest CT scans

Figure 71-2 Bleomycin-induced lung disease. A chest CT scan of bleomycin pneumonitis showing a nodular pattern (arrows). The histologic features of this form of bleomycin-induced lung injury are typical of organizing pneumonia.

were abnormal in 38%, whereas the chest radiographs were abnormal in only 15%.²⁶ Serial imaging studies are not recommended in the absence of specific symptoms.

Other forms of bleomycin-induced lung disease have been described, albeit less commonly. Hypersensitivity reactions (eFig. 71-1) are possible with an association of fever and peripheral blood or BAL eosinophilia.^{14,15} Discontinuation of bleomycin and initiating corticosteroids usually bring about rapid reversal of this hypersensitivity variant of bleomycin pneumonitis.

An additional rare, but clinically important, presentation of bleomycin pneumonitis is that of nodular pulmonary lesions mimicking tumor metastasis (Fig. 71-2).²⁷ These reactions to bleomycin have been described in the setting of lymphoma or seminoma, requiring surgical biopsy to differentiate bleomycin-associated lung injury from recurrence of the primary malignancy. Although bleomycin pulmonary toxicity may reflect diffuse alveolar damage (eFig. 71-2A), these nodular lesions from bleomycin often exhibit the histologic pattern of organizing pneumonia (see eFig. 71-2B).⁶ Pneumothorax and pneumomediastinum have also been described.

In suspected cases of bleomycin lung toxicity, discontinuation of the drug is warranted. Administration of corticosteroids is often recommended. It would seem prudent to pay particular attention to avoid high fractions of inspired oxygen and concomitant radiotherapy and to monitor the kidney function carefully during the duration of treatment. One study demonstrated that, if the patient survives the acute injury from bleomycin, pulmonary findings might improve substantially over time (see eFig. 71-1).²⁸ However, if significant fibrosis is present, the process may progress insidiously despite the administration of corticosteroids. Histologic, end-stage bleomycin pneumonitis may appear similar to the usual interstitial pneumonia pattern.

Mitomycin C

Mitomycin C is another antibiotic chemotherapeutic agent associated with pulmonary toxicity, which shares features

similar to those induced by bleomycin. It has been employed in the management of bladder tumors, lung cancer, anal cancer, metastatic breast carcinoma, metastatic liver tumors, and esophageal malignancies. One series estimated the incidence of mitomycin-induced pneumonitis to be approximately 8%, with two additional series suggesting the incidence ranged from 12% to as high as 39%.^{29,30} Similar to bleomycin-induced lung toxicity, the cumulative dose appears associated with the incidence of pulmonary manifestations in a linear fashion, with pulmonary fibrosis unlikely at doses less than 30 mg/m². Again, high fraction of inspired oxygen and radiotherapy may exacerbate this phenomenon. Concomitant administration of other chemotherapeutic agents such as bleomycin, doxorubicin, or cyclophosphamide may enhance pulmonary toxicity.

The symptomatology, imaging abnormalities, and histologic findings of mitomycin-induced pneumonitis are similar to those of other alkylating drug toxicities. However, it has been suggested that the DL_{CO} may not fall before the onset of clinical symptoms, making it an unreliable predictor of overt lung disease.³⁰ In addition, a favorable response to corticosteroid therapy has also been quite dramatic in many of these patients, possibly greater than in other forms of chemotherapy-associated lung injury.

In addition to mitomycin-induced pneumonitis, there are reports of an unusual reaction to mitomycin C consisting of microangiopathic hemolytic anemia with associated noncardiogenic pulmonary edema and renal failure, in particular when associated with 5-fluorouracil.³¹ This may be associated with pulmonary hypertension. Most of these patients developed side effects between 6 and 12 months after beginning mitomycin C chemotherapy. Up to one half of these patients evolve into the *acute respiratory distress syndrome* (ARDS), with mortality as high as 95% in some series. The mortality in patients with mitomycin C-associated hemolytic uremic syndrome who do not develop acute respiratory distress syndrome is still in the range of 50%. In some instances, this unusual drug reaction appears to be precipitated by blood transfusions. Microangiopathic changes are present in the lungs and kidneys with intimal hyperplasia of the arterioles, along with prominent nuclear atypia of the capillary cells and capillary fibrin thrombi. Treatment is essentially supportive, with initiation of plasma exchange with or without dialysis and corticosteroids when deemed appropriate.

Pulmonary veno-occlusive disease (PVOD) has also been rarely reported in patients receiving mitomycin C. In one case report, PVOD was confirmed on autopsy.³²

Other Antibiotic Chemotherapeutic Agents

A variety of other antibiotic chemotherapeutic agents have been associated with respiratory complications, although the nature of combined chemotherapeutic regimens makes it difficult to attribute the responsibility to one drug instead of another. *Doxorubicin* is an anthracycline agent notorious for causing cumulative cardiotoxicity with possible cardiogenic pulmonary edema. Rare cases of interstitial pneumonias have also been described, usually in combination with other drugs, typically with mitomycin C. Organizing pneumonia has rarely been reported. Infusion reactions with dyspnea may be observed in 5% to 10% of patients treated with pegylated liposomal doxorubicin. *Epirubicin* is

a similar compound with fewer side effects. Pulmonary complications are rare but may be seen in conjunction with other chemotherapeutic agents. *Mitoxantrone* is an anthracenedione inhibitor of topoisomerase II used in the treatment of multiple sclerosis, acute lymphoid leukemia, acute myeloid leukemia, breast cancer, liver cancer, non-Hodgkin lymphoma, and prostate cancer. Rare cases of subacute interstitial pneumonias have been described. *Actinomycin D* has also been associated with reactivation of prior radiation pneumonitis.²³

ALKYLATING AGENTS

Busulfan

Busulfan has been used for the management of chronic myeloproliferative disorders. It was discovered in 1961 and found to be responsible for significant pulmonary toxicity shortly after. The average duration from the initiation of therapy to the onset of respiratory symptoms is roughly 3.5 years, ranging between 8 months and as late as 10 years. However, busulfan pulmonary toxicity can develop as soon as 6 weeks following initiation of therapy. The incidence of busulfan pulmonary toxicity is estimated to be 6%, with a reported range of 2.5% to 43%.³³ The mortality rate is extremely high, in the range of 80%.²³ No effective therapy has been identified, and discontinuation of the drug with or without initiation of corticosteroid therapy, although recommended, is of unclear value. No obvious aggravating factors have been identified, except perhaps the concomitant administration of other chemotherapeutic agents or radiotherapy. Age and cumulative dose do not seem to play any important role.

Dyspnea, fever, and cough begin in a more insidious fashion with busulfan than with many other chemotherapy lung toxicities. Such symptoms have even been reported to begin months after busulfan therapy has been discontinued. The chest radiograph in busulfan toxicity reveals a combined alveolar and interstitial process to a greater degree than in other chemotherapy reactions. This is likely due to a high degree of desquamation of injured epithelial cells into the alveolar spaces. This alveolar debris may be so extensive as to suggest pulmonary alveolar proteinosis in some patients receiving busulfan. This form of alveolar proteinosis is more refractory to therapeutic lavage than is idiopathic pulmonary alveolar proteinosis. Busulfan-induced pulmonary toxicity is characterized by the presence of acute lung injury with associated atypical type II pneumocytes with markedly enlarged pleomorphic nuclei and prominent nucleoli (eFig. 71-3).

Cyclophosphamide

Cyclophosphamide is widely included in combination chemotherapy for hematologic malignancies and solid tumors. It is also used in the treatment of granulomatous polyangiitis. The incidence of pulmonary toxicity is estimated at around 1%, although accumulating evidence suggests that it may be much more common. A case series from a large tertiary referral center only identified six patients older than 20 in whom cyclophosphamide was the only factor contributing toward pulmonary injury.³⁴ Clinical features of cyclophosphamide-associated pulmonary toxicity include

fever, dyspnea, cough, gas-exchange abnormalities, parenchymal opacities, and pleural thickening. Two patterns of cyclophosphamide-induced lung toxicity have been described. First, there can be an early-onset pneumonitis within the first 1 to 6 months after institution of therapy. This form generally responds to withdrawal of cyclophosphamide. In contrast, there may also be a late-onset pneumonitis that may develop after months or even years of therapy and result in progressive lung fibrosis and bilateral pleural thickening. This late-onset variety unfortunately has minimal response to withdrawal of cyclophosphamide or to corticosteroid therapy.³⁴ The dose of cyclophosphamide and development of lung disease are not clearly related. Supplemental oxygen and radiotherapy may increase the likelihood of lung manifestations. Likewise, concomitant administration of other agents such as bleomycin, and perhaps carmustine, in preparation before bone marrow transplantation seems to accentuate the phenomenon. There have also been rare reports of rechallenge with cyclophosphamide without subsequent recurrence of the pulmonary toxicity. For obvious reasons, this is generally not recommended.

Chlorambucil

This agent has been prescribed primarily for chronic lymphocytic disorders. The clinical presentation, chest radiographic abnormalities, and histologic features of chlorambucil-associated pneumonitis are remarkably similar to those described in other alkylating agent–induced pulmonary toxicities.⁸ Cumulative doses in excess of 2 g seem to increase the risk significantly. The presentation is usually insidious, happening 6 months to a year or more after the start of therapy. Surveillance of lung function, particularly DL_{CO}, may be of benefit in anticipating which patients will deteriorate and require discontinuation of the agent. Few data are available on the efficacy of corticosteroid therapy in chlorambucil-related lung toxicity.

Melphalan

Melphalan has been enlisted in the treatment of multiple myeloma. There have been relatively few well-documented cases of pulmonary toxicity associated with melphalan.³⁵ The course of melphalan-associated pulmonary injury varies from acute to more subacute in tempo. Patients present with insidious to abrupt onset of dyspnea, cough, and frequently fever. There are no particular clues for predicting which patients will develop side effects. The incidence of pulmonary side effects from melphalan must be generally low, in view of the fact that this agent has been widely employed in the long-term management of myeloma.

Ifosfamide

Ifosfamide is structurally related to cyclophosphamide and has been used in the treatment of a variety of solid tumors, including lung, testicular, and breast cancer. Case reports of subacute interstitial pneumonias can be found in the literature, although the responsibility of ifosfamide remains unclear, as it was used in combination with other chemotherapeutic agents such as docetaxel. One case of fatal acute pneumonitis primarily due to ifosfamide has been reported. A case of methemoglobinemia has also been

described, presumably secondary to the interaction between 4-thioifosfamide, a metabolite of ifosfamide, and glutathione and resultant oxidative stress.³⁶

Other Alkylating Agents

Procarbazine is primarily used in the treatment of Hodgkin lymphoma and glioblastoma multiforme. Rare cases of interstitial pneumonias have been reported, sometimes characterized by significant eosinophilia suggesting a hypersensitivity reaction. Progression to widespread and irreversible fibrosis seems rare.³⁷

Oxaliplatin has been associated with laryngeal dysesthesia and was thought to be responsible for the development of diffuse alveolar damage, often in association with 5-fluorouracil. More typically, there can be severe anaphylactic reactions during infusion of the drug in about 1.3% of the cases. Eosinophilic pneumonia has also been rarely reported.^{38,39}

Temozolomide is a second-generation alkylating agent now considered standard of care as an adjuvant therapy for glioblastoma in association with radiotherapy. It is also used in the treatment of metastatic melanoma. Few respiratory side effects have been described, mainly pharyngitis, sinusitis, cough, upper respiratory tract infection, and dyspnea. Pneumonitis was found in up to 4.8% of patients in Phase II trials. One case of organizing pneumonia that resolved after discontinuation of treatment was described.⁴⁰

Chlorozotocin, an alkylating agent used in the treatment of neuroendocrine tumors, has been associated with several cases of mild pneumonitis. All cases resolved with discontinuation of the drug and administration of corticosteroids.⁴¹

ANTIMETABOLITES

Methotrexate

Methotrexate is present in many combination regimens for malignancies and is also used extensively for nonmalignant conditions, including psoriasis and rheumatoid arthritis. It interferes with the metabolism of folic acid, hence specifically targeting replicating cells and leading to a variety of well-described adverse effects, including bone marrow suppression, mucositis, alopecia, and gastrointestinal manifestations. Pulmonary toxicity is thought to develop in about 10% of all patients treated but is fortunately rarely fatal. Dyspnea, nonproductive cough, and fever usually commence a few days to several weeks after initiation of therapy. However, in rare cases, symptoms may be observed a few months or years after onset of therapy.⁴²

Methotrexate-associated pneumonitis (eFig. 71-4) is almost always reversible with or without the addition of corticosteroids. Eosinophilia is seen in at least half of the cases, and the disease is therefore believed to represent a hypersensitivity reaction.¹⁴ The intriguing feature of this reaction is that the drug may be reinstituted following resolution of methotrexate pneumonitis without necessarily triggering a subsequent recurrence of symptoms or findings.⁴³ In about one third of the patients, weakly formed granulomas are identified in lung biopsy, which is unusual in other forms of chemotherapy-associated lung disease (eFig. 71-5).⁶ Hilar lymphadenopathy is occasion-

ally present, and this might mimic the manifestations of sarcoidosis. There is no cellular atypia, such as is seen in many other cytotoxic drug toxicities.

The chest radiograph tends to reveal a homogeneous opacity throughout all lung fields. Hilar adenopathy or pleural effusion is seen in at least 10% to 15% of patients with methotrexate lung toxicity. In distinct contrast to most of the other chemotherapy-induced pulmonary toxicities, prospective investigations of patients receiving methotrexate have not demonstrated a diminished DL_{CO} that might predate subclinical toxicity. In addition, pulmonary toxicity in response to methotrexate does not appear to be dose related. There have been a few reports of fatal reactions either from intrathecal methotrexate or from oral ingestion after previous intrathecal injections. Two other important manifestations associated with methotrexate should be mentioned. Opportunistic infections related to T-cell deficiency need to be excluded, in particular *Pneumocystis* pneumonia, which has been reported in a number of patients receiving methotrexate, either alone or in combination with corticosteroids.⁴⁴ Peculiar Epstein-Barr virus-related lymphomas that typically resolve after discontinuation of treatment have also been reported and may be directly related to an alteration in immune surveillance induced by methotrexate (as seen in posttransplantation lymphoproliferative disorders). The clinical presentation, chest radiography, and other clinical features can be quite similar to methotrexate lung.⁴⁴

Azathioprine and 6-Mercaptopurine

More than two dozen case reports of azathioprine-associated pneumonitis have been reported. However, the net overall incidence must be low, considering the widespread use of this agent for neoplastic and non-neoplastic conditions.³⁵ Nevertheless, the possibility of an azathioprine pneumonitis must be considered in any individual receiving this agent. Azathioprine is metabolized to 6-mercaptopurine, and there have been a handful of reports detailing cytotoxic interstitial pneumonitis in association with this metabolite.⁵ However, most of these patients have also received other agents that potentially could be implicated in the lung injury described.

Cytosine Arabinoside

Cytosine arabinoside (ara-C) is a cytotoxic agent used to induce remission in acute leukemia and other hematologic malignancies before bone marrow transplantation. Intensive ara-C treatment regimens have been associated with rapidly fatal noncardiac pulmonary edema (Fig. 71-3).⁵ Histologic examination of lung tissue during ara-C pulmonary toxicity reveals substantial accumulation of intra-alveolar proteinaceous material without the cellular atypia and mononuclear infiltration described with other cytotoxic drugs. In two large series, 13% to 28% of the patients with toxicity developed respiratory distress during the administration of the drug, and nearly one half developed symptoms within a month of completing drug administration. The mechanism underlying this reaction is unknown, and the associated mortality is high. Treatment for ara-C pulmonary toxicity is largely supportive, with mechanical ventilation, careful management of fluid status, and surveillance for superimposed infectious complications.

Figure 71-3 Cytosine arabinoside-induced lung disease. A chest radiograph of a 44-year-old woman showing acute noncardiac pulmonary edema that resulted from cytosine arabinoside-induced lung disease. Histologic examination typically demonstrates intense intra-alveolar proteinaceous material forming hyaline membranes, but little other reaction.

Gemcitabine

Gemcitabine is a pyrimidine analogue, with structure and activities similar to ara-C. It is highly active against non-small cell lung cancer, as well as breast, pancreatic, and ovarian cancers. It is usually well tolerated, with the most prevalent toxicity being bone marrow suppression, as well as nausea, rash, transaminase elevation, and edema in some cases. The incidence has probably been underestimated. Dyspnea has been reported in 10% of treated patients, with severe dyspnea reported in up to 5%.⁴⁵⁻⁴⁷ Noncardiogenic pulmonary edema is thought to develop in 0.1% to 7% of all patients treated.⁴⁸ There are three major patterns of respiratory involvement in gemcitabine-related pulmonary toxicity. The first pattern is a nonspecific, self-limiting dyspnea reported within hours to days of treatment. A second, relatively uncommon, pattern is that of an acute hypersensitivity reaction with bronchospasm. A third pattern of severe respiratory involvement is occasionally seen. This is a severe idiosyncratic reaction with profound dyspnea and pulmonary opacities that may progress to life-threatening respiratory insufficiency within hours of infusion (Fig. 71-4). Most cases of gemcitabine-related pulmonary toxicity resolve with discontinuation of this drug. In cases of severe symptoms, discontinuation of the agent along with institution of corticosteroids, careful fluid management, and diuretic therapy may be warranted.⁴⁵ Cases of diffuse alveolar hemorrhage, pulmonary veno-occlusive diseases, and thrombotic microangiopathy have also been described.

Fludarabine

Fludarabine, another nucleoside analogue, is widely employed in the management of chronic lymphoproliferative disorders. The incidence of pulmonary toxicity related to fludarabine has been estimated to be approximately 8.6% in a series of 105 patients.⁴⁹⁻⁵¹ Affected individuals experi-

Figure 71-4 Gemcitabine-induced lung disease. A chest CT image of an individual with gemcitabine-induced lung disease. The pattern is a mixed alveolar and interstitial infiltration.

ence dyspnea as early as 3 days after the first round of chemotherapy, though later onset of pulmonary symptoms has also been reported. The chest radiograph reveals either interstitial or mixed alveolar-interstitial opacities. Nodular opacities have also been described. As is often the case with chemotherapeutic agents, particular attention should be given to the possibility of opportunistic infections. Most patients respond to discontinuation of the drug and receive symptomatic and objective benefits from additional corticosteroid therapy.

Piritrexim

Piritrexim is an oral inhibitor of the dihydrofolate reductase used in the treatment of parasitic infections, psoriasis, and transitional cell carcinoma. It is closely related to methotrexate, and pulmonary toxicity has been observed in up to 14% of patients.⁵²

Nitrosoureas

Nitrosourea compounds have a role in the treatment of gliomas and other central nervous system tumors, as well as in conditioning protocols preceding autologous bone marrow stem cell transplantation. Pulmonary toxicity related to nitrosoureas is well recognized and represents one of the most common side effects of these agents.⁵³ In particular, *bischloroethyl nitrosourea* (BCNU, carmustine) has been described to induce both acute-onset pulmonary injury (see eFig. 91-13) and delayed-onset pulmonary fibrosis, with a predilection for the upper lobes.⁵³ The incidence of pulmonary toxicity associated with the administration of BCNU varies from 1.5% to 20% and is dose related, with up to a 50% incidence of lung disease in those receiving a total dose of greater than 1500 mg/m². However, there have also been reports of pulmonary effects with much lower doses. The duration of therapy before the onset of pulmonary toxicity for the acute variant of nitrosourea lung injury has generally ranged from 6 months to 3 years. There appears to be a synergistic effect with cyclophosphamide, radiation therapy, and possibly other chemotherapeutic agents. The outcome may be unpredictable and sometimes fatal. There have been fewer case reports of pulmonary toxicity with *methyl-chloroethyl cyclohexyl nitrosourea* (methyl-CCNU) and *chloroethyl cyclohexyl nitrosourea* (CCNU). Apparently, fever is less commonly associated with this form

of pulmonary toxicity than with many other chemotherapeutic drugs. Therapy usually consists of withholding the offending agent and institution of corticosteroids, which has variable and often only transient beneficial effects.⁵⁴

A long-term complication of BCNU toxicity is upper lobe fibrosis that may appear many years after the completion of chemotherapy. O'Driscoll and colleagues⁵⁵ followed 17 patients for up to 17 years, and 12 of the 17 (71%) developed delayed upper lobe fibrosis. The fibrosis is insidious in onset and, once discovered, appears to be intractably progressive. Corticosteroid therapy has not proven to be effective in delayed BCNU upper lobe fibrosis. Another unusual reported complication that is almost exclusively associated with nitrosourea compounds is pneumothorax.⁵⁶ This may be related to the upper lobe fibroblastic changes present in patients with BCNU lung toxicity.

Cases of pulmonary fibrosis have also been reported with other nitrosourea agents, including lomustine (CCNU), semustine (methyl-CCNU), fotemustine (CENU), and chlorozotocin (DCNU). Pneumothoraces have rarely been described with these agents.

PODOPHYLLOTOXINS

Etoposide and Teniposide

Etoposide (VP-16), a topoisomerase II inhibitor, has been widely used in combination chemotherapy for non-small cell and small cell lung carcinoma. Despite its extensive use, only a few cases of etoposide-associated pulmonary toxicity have been reported.⁵⁷ Toxicity may become apparent shortly after the first round of chemotherapy, although most of the associated cases present after prolonged treatment. Tissue examination reveals features of alveolar edema, diffuse alveolar damage, and atypical type II pneumocytes. Therapy consists of withdrawal of the agent and administration of corticosteroids, which provide variable improvement. In addition, etoposide may increase the intracellular levels of methotrexate and thus, the combination of methotrexate and etoposide may synergistically increase the likelihood of adverse reactions.

Teniposide, another podophyllotoxin agent, is also associated with hypersensitivity reactions in 3.6% to 6.5% of the cases. This toxicity may present with dyspnea, bronchospasm, and hypertension.⁵²

Paclitaxel

Paclitaxel is a highly potent chemotherapeutic agent used in the treatment of lung, breast, and ovarian carcinomas. Well-documented cases of pulmonary toxicity induced by paclitaxel can be found in the literature, but the frequency is unclear. Patients may complain of respiratory symptoms including cough, dyspnea, wheezing, and chest tightness within minutes of administration of the drug, suggesting a type I hypersensitivity reaction. Immunoglobulin E antibodies against paclitaxel itself or perhaps its vehicle, Cremophor EL, are thought to be responsible.⁵⁸ This reaction may be seen in up to 30% of patients, and premedication with corticosteroids is sometimes considered. Reticular and nodular opacities have been reported on chest radiographic studies.⁵⁹ Cases of transient pulmonary opacities and suspected interstitial pneumonitis have also been described

(eFig. 71-6). The true incidence of lung toxicity directly related to paclitaxel is not well understood. A prospective study of lung function in 33 patients receiving paclitaxel with carboplatin (an agent with little lung toxicity) in the setting of nonthoracic malignancy revealed an isolated decrease in DL_{CO} without other clinical or radiographic evidence of pulmonary toxicity.⁶⁰ In other studies, conducted on patients with lung carcinoma, significant early and late pulmonary toxicity has been noted in 10% and 68% of patients, respectively.^{61,62} Attributing the toxicity directly to paclitaxel is confounded by the underlying thoracic neoplasm, as well as other cytotoxic agents used in these patients.⁶¹ Nonetheless, clinicians should be aware of the potential of paclitaxel impairing pulmonary function.

Docetaxel

Docetaxel (Taxotere) is another taxane compound that has activity in the treatment of breast and non-small cell lung cancer. Occasional pulmonary toxicity based on a hypersensitivity reaction has been observed.⁶³ These patients have responded rapidly to corticosteroid therapy. A small case series has suggested that the combination of docetaxel and gemcitabine has a particular propensity to induce severe pulmonary toxicity.⁶⁴ Some patients may develop capillary leak syndrome with peripheral edema, noncardiogenic pulmonary edema, and/or pleural effusions.^{65,66} The severity of fluid retention can be reduced by prophylactic treatment with corticosteroids.⁶⁷

VINBLASTINE

Vinblastine, a vinca plant alkaloid, is one of the oldest chemotherapeutic agents still in use. Vinblastine continues to be included in a wide variety of chemotherapeutic regimens for hematologic and solid malignancies. Traditionally, vinblastine was thought to have little if any pulmonary toxicity. However, reports have associated vinblastine with pulmonary complications when it is combined with other agents, particularly mitomycin C. This combination has been complicated by bronchospasm, interstitial pneumonitis, and a noncardiac pulmonary edema.^{68,69}

ALL-TRANS RETINOIC ACID

All-trans retinoic acid (ATRA) has been employed in acute promyelocytic leukemia, in which it promotes differentiation of myeloid precursors and stimulates the maturation of leukemic cells, thereby promoting remission. It has also been reported to reduce disseminated intravascular coagulation and hemorrhagic complications during promyelocytic leukemia. The main complication limiting its use is the development of the differentiation syndrome (previously called retinoic acid syndrome) in up to 25% of patients treated. This syndrome consists of diffuse edema, pleuro-pericardial effusions, and noncardiogenic pulmonary edema that may evolve into a generalized capillary leak syndrome (eFigs. 71-7 and 71-8). Hypotension and acute renal failure are commonly present. Toxicity may manifest suddenly between days 2 and 21 of treatment. Its pathogenesis remains elusive, but it is thought to result from a massive release of cytokines from newly mature myeloid cells and adhesion of granulocytes to the pulmonary

endothelium. Indeed, high leukocyte counts have been associated with an increased incidence of the syndrome in some, but not all, studies. In addition, multiple hemorrhagic complications have also been described. In one study, 9 of 35 patients with promyelocytic leukemia receiving ATRA developed respiratory distress.⁷⁰ Intravenous corticosteroid therapy seemed to be of benefit to these patients. On the basis of these observations, an additional study has suggested that the incidence of ATRA-associated pulmonary complications may be reduced to roughly 10% through the use of preventative treatment with oral corticosteroids.

The mortality associated with ATRA-induced pulmonary toxicity is estimated at around 9%. Tissue examinations of lungs affected by ATRA have revealed interstitial infiltration with maturing myeloid cells. However, the overall spectrum of the ATRA-associated pulmonary syndrome is continuing to evolve and includes the presence of myeloid cells and blasts in BAL fluid, nodular pulmonary opacities, pulmonary leukostasis, noncardiogenic pulmonary edema, ARDS, Sweet syndrome, and diffuse alveolar hemorrhage.⁷¹

IRINOTECAN AND TOPOTECAN

Irinotecan, a semisynthetic camptothecin, has been employed for advanced colorectal cancer either alone or in combination with 5-fluorouracil, as well as in some lung cancer trials. Early studies of irinotecan in Japan documented a 1.8% incidence of pneumonitis.⁷²⁻⁷⁴ In those studies, clinical features included dyspnea, fever, and reticulonodular pulmonary opacities. Empirical corticosteroids were recommended, but some patients progressed to fatal respiratory failure. In subsequent U.S. trials, cough and dyspnea were described in roughly 20% of treated patients.⁷⁵ However, many of these patients had intrathoracic malignancies. The reported incidence of serious pulmonary toxicity related to irinotecan was much lower in these subsequent trials ($\approx 0.4\%$).⁷⁵ Radiotherapy and preexisting lung disease may increase the risk. Nonetheless, cases of serious irinotecan-associated interstitial pneumonitis have been reported in the United States. Patients with preexisting pulmonary disease may be at enhanced risk.

Topotecan is a similar agent and has rarely been reported to induce pulmonary toxicity, including cases of diffuse alveolar damage and constrictive bronchiolitis.

TARGETED THERAPY

Monoclonal Antibodies

As our understanding of the pathogenesis of malignant processes continues to increase, the identification of specific target tumoral antigens has led to the development of specific immunotherapeutic tools, including monoclonal antibodies. Several new molecules have emerged as potentially beneficial adjunct agents in a variety of neoplastic processes.

Bevacizumab. Bevacizumab (Avastin) is a monoclonal antibody targeting the vascular endothelial growth factor, and designed to inhibit tumoral neoangiogenesis. It has been used in conjunction with conventional chemothera-

peutic agents in the treatment of metastatic colon, renal cell cancer, breast cancer, sarcoma, ovarian cancer, glioblastoma, and nonsquamous non-small cell lung cancers. It is associated with hemorrhagic complications including fatal pulmonary hemorrhage thought to result from extensive tumor necrosis. These complications have been predominantly seen in patients with squamous cell lung cancer. Although it may seem counterintuitive, bevacizumab is thought to increase the incidence of thromboembolic disease by twofold. This may be secondary to vascular injury with secondary exposure of the underlying endothelium with secondary activation of the coagulation cascade. Cases of thrombotic microangiopathy with hypertension and acute renal failure have also been described. Cases of congestive heart failure have also been described, mostly in association with anthracycline agents, raising questions about this reported association.⁷⁶ Tracheoesophageal and bronchoesophageal fistulas have been described in patients treated with bevacizumab for lung cancer.⁷⁷⁻⁷⁹

Cetuximab and Panitumumab. Cetuximab and panitumumab are two monoclonal antibodies directed against the *epidermal growth factor receptor* (EGFR) that are increasingly used in treatment of a number of neoplasms. Both have been associated with rare pulmonary toxicity. Interstitial lung disease has been reported in 0.4% of patients with cetuximab, and there may be infusion reactions with bronchospasm and hoarseness in 23% of the cases. With panitumumab, there may be similar infusion reactions, which may be severe in 1% of the cases. Panitumumab has now been associated with an increasing number of interstitial lung disease and pulmonary fibrosis cases. The interstitial lung disease has been found to be fatal in some cases, so if toxicity becomes apparent, panitumumab should be stopped and steroids should be considered.^{80,81}

Trastuzumab and Ado-Trastuzumab Emtansine. Trastuzumab selectively binds the *human epidermal growth factor receptor-2* (HER-2) protein and is an adjuvant treatment of metastatic HER-2-positive breast cancer. As seen with other monoclonal antibodies, infusion reactions may present in 15% of the cases and are potentially associated with angioedema, fever, and bronchospasm. Trastuzumab reactions may also present as an acute or subacute interstitial pneumonia in approximately 0.5% of the cases, with a mortality rate estimated at 0.1%.⁸² An increasing number of case reports suggest that interstitial pneumonia is likely a rare but real toxicity of trastuzumab. Ado-trastuzumab is an antibody-drug conjugate that contains trastuzumab and a cytotoxic microtubule inhibitor. It is also used in breast cancer and has been associated with acute pneumonitis. The incidence is low at 0.8% to 1.2% but may be life-threatening, so if pneumonitis develops, ado-trastuzumab should be discontinued.⁸³

Rituximab. Rituximab is an anti-CD20 chimeric monoclonal antibody approved in 1997 for the treatment of non-Hodgkin lymphoma. Its ever-increasing indications have led to an exponential increase in its use in a variety of diverse conditions from autoimmune inflammatory diseases to posttransplantation lymphoproliferative disorders. The most common side effect of rituximab is an infusion

reaction in more than 50% of patients. Symptoms include fever, chills, dyspnea, hypotension, rhinitis, urticaria, pruritus, and a sensation of throat and tongue swelling. Slowing or stopping the rituximab infusion may help resolve the symptoms. Corticosteroids are occasionally required. Other pulmonary complications of rituximab appear fairly rare overall. A review of the literature in 2007 only identified 16 cases of interstitial lung disease assumed to be secondary to rituximab use. Specific patterns of lung injury have also been described in pathologic specimens, including diffuse alveolar hemorrhage and desquamative interstitial pneumonia, but the experience is often limited to isolated case reports.⁸⁴

Tyrosine Kinase Inhibitors

Gefitinib. Gefitinib (Iressa) is a selective EGFR tyrosine kinase inhibitor used in patients with advanced non-small cell lung cancer and EGFR-activating mutations. Acute interstitial pneumonia has been associated with this drug, and the overall incidence of gefitinib-associated interstitial lung disease may be in the range of 1%, with a mortality rate approaching 30%.^{85,86} The most common presentation is acute dyspnea with or without cough or fever.⁸⁵ The median onset of symptoms was 24 to 31 days in Japanese and 42 days in American patients.⁸⁵ Diffuse ground-glass opacities and multifocal airspace consolidation have been reported on CT scan.⁸⁷ Tissue examination demonstrates diffuse alveolar damage, interstitial inflammation with or without fibrosis, and organizing pneumonia.^{86,88-90} Although some patients respond to withdrawal of the agent and institution of corticosteroid therapy, others progress to fulminant respiratory insufficiency. Hence the clinician needs to remain mindful of this pulmonary complication of gefitinib therapy and discontinue the agent if symptoms and radiographic abnormalities develop. The benefit of corticosteroids is unclear.

Erlotinib. Erlotinib (Tarceva), another EGFR antagonist, is used widely in the United States for the treatment of advanced lung adenocarcinomas with EGFR mutations. Erlotinib has also been rarely associated with pulmonary toxicity including fatalities.⁹¹⁻⁹³ Patients who have undergone lung biopsy have shown organizing pneumonia or diffuse alveolar damage.⁹³ The presentation is similar to most drug-induced lung injury with dyspnea, cough, and low-grade fever. The median time to toxicity is 47 days.⁹¹ Treatment is supportive with removal of the drug. The benefit of corticosteroids is unclear.

Imatinib. Imatinib (Gleevec) is an inhibitor of the Bcr-Abl, KIT, and *platelet-derived growth factor receptor* (PDGFR) tyrosine kinases. It is used in the treatment of chronic myelogenous leukemia and gastrointestinal stromal tumors.⁹⁴ Fluid retention causing peripheral, periorbital, and pulmonary edema is a common complication.⁹⁵⁻⁹⁷ There have been cases reported of pulmonary infiltration with eosinophilia or acute interstitial pneumonia.^{94,98-101} Symptoms of dyspnea, cough, and low-grade fever develop at a median time of 49 days.¹⁰² Radiographic studies have shown ground-glass opacities, consolidation, or nodular opacities. BAL findings demonstrate lymphocytes, foamy macrophages, and, in some cases, eosinophilia.^{101,103,104}

Peripheral eosinophilia has also been demonstrated.¹⁰³ Lung biopsies have demonstrated interstitial inflammation and fibrosis, alveolitis, and pulmonary alveolar proteinosis.^{99,103,104} Treatment is removal of the drug and, in many cases, corticosteroids. Rechallenge of the drug does not always cause recurrence of the lung injury, so physicians must carefully consider alternative agents and the risk and benefit of rechallenge.^{103,105}

Dasatinib. Dasatinib is a Bcr-Abl tyrosine kinase inhibitor that is used to treat Philadelphia chromosome-positive chronic myeloid leukemia. Dasatinib is associated with pleural effusions, pulmonary hypertension, and pulmonary parenchymal abnormalities. Pleural effusions have been reported in 10% to 35% of patients treated.¹⁰⁶⁻¹¹⁰ Effusions are mostly lymphocytic and exudative. Concomitant lung disease and higher initial daily dose were risk factors for development of pleural effusions.¹⁰⁸ Treatment of the pleural effusions is unclear but has included glucocorticoids, diuretics, thoracentesis, and discontinuation of dasatinib.^{106,108,111,112} Pulmonary arterial hypertension is a rare complication of dasatinib use with symptom onset after 8 to 48 months of therapy.¹¹³⁻¹¹⁷ Presenting symptoms included tachypnea, exertional dyspnea, fatigue, and peripheral edema.¹¹³⁻¹¹⁷ Dasatinib therapy should be discontinued if pulmonary hypertension develops, and there should not be a rechallenge of the drug.¹¹³⁻¹¹⁷ Pneumonitis is another rare complication of dasatinib. In one study of patients treated with dasatinib, 40 (23%) patients developed a lung abnormality.¹¹⁸ The lung changes resolved or partially resolved in all 9 patients with parenchymal abnormalities.¹¹⁸ Discontinuation of dasatinib resulted in resolution in 5 patients, and glucocorticoids were used in 1 patient with complete resolution.¹¹⁸ Rechallenge with dasatinib can be considered in patients with parenchymal abnormalities.¹¹⁸

Bosutinib. Bosutinib is another tyrosine kinase inhibitor that targets Bcr-Abl and is used to treat Philadelphia chromosome-positive CML. Like dasatinib, pleural effusion is the most common pulmonary toxicity.¹¹⁹

Sunitinib and Sorafenib. Sunitinib and sorafenib are small molecule tyrosine kinase inhibitors that block the intracellular domain of the *vascular endothelial growth factor* (VEGF) receptor. Sunitinib is used to inhibit angiogenesis in the treatment of gastrointestinal stromal tumors and renal cell cancer. Sunitinib has been reported to cause dyspnea and cough.¹²⁰ Pulmonary embolism has also rarely been reported. Sorafenib is used to inhibit angiogenesis in renal cell carcinoma and unresectable hepatocellular carcinoma. Pulmonary toxicity has been reported during sorafenib use with diffuse pulmonary opacities, dyspnea, cough, and fever.¹²¹ Although a rare toxicity, it was fatal in some patients, so the drug should be stopped immediately if pulmonary toxicity is suspected.¹²¹

Immunomodulatory Agents

Interferons. Interferons have been used in a wide variety of malignant, infectious, and inflammatory disorders. Interferon-alfa and interferon-beta have been employed in the treatment of hairy cell leukemia, myeloma, T-cell

lymphoma, chronic myelogenous leukemia, malignant pleural effusions, melanoma, renal cell carcinoma, and Kaposi sarcoma. Interferon-gamma has been included in investigative trials for mesothelioma, non-small cell lung carcinoma, and idiopathic pulmonary fibrosis.

Administration of interferons has been associated with a variety of pulmonary reactions. For instance, interferon- α has been linked to severe exacerbation of bronchospasm in patients with preexisting asthma.¹²² In addition, a granulomatous reaction indistinguishable from sarcoidosis (eFig. 71-9) has been described in relation to interferon therapy.¹²³ These toxicities usually respond to either reduction or withdrawal of the interferon treatment with or without the addition of corticosteroids. Noncaseating granulomas have been documented in the lung, lymph nodes, liver, and skin of affected patients.

Interferon-associated interstitial lung disease has also been reported.¹²⁴ Dyspnea and cough are observed and bilateral opacities are present on chest radiography. A CD8-predominant lymphocytic response is found in the BAL fluid, and a cellular interstitial pattern is present on histology. In some cases, interferon therapy has also been associated with an organizing pneumonia pattern.¹²⁵ Most affected patients respond to discontinuation of the interferon and administration of corticosteroids. Recently, interferon-gamma has been used in idiopathic pulmonary fibrosis. A series has been reported in which four patients with advanced idiopathic pulmonary fibrosis developed acute hypoxemic respiratory failure during interferon-gamma treatment.¹²⁶ This was not responsive to corticosteroids and was fatal in three cases. Interferon-gamma is also associated with a high incidence of severe radiation pneumonitis when it is used in multimodality therapy for non-small cell lung carcinoma.

Rapamycin Analogs. Sirolimus was initially developed as an antifungal agent isolated from *Streptomyces hygroscopicus*. It is a macrolide antibiotic inhibitor of the mammalian target of rapamycin (mTOR) with antiproliferative and immunosuppressive properties essentially used to prevent rejection in solid-organ transplantation and as a coating agent in drug-eluting stents. It is currently under investigation for the treatment of lymphangiomyomatosis.¹²⁷ Several patterns of drug toxicity have been described with sirolimus, including the subacute onset of interstitial pneumonitis (eFig. 71-10) (which usually resolves after discontinuation of therapy), an organizing pneumonia injury pattern, and diffuse alveolar hemorrhage. Rare cases of alveolar proteinosis and granulomatosis have also been reported. Typically, these pulmonary complications are reversible after discontinuation of therapy, but occasionally they represent a difficult diagnostic challenge in an immunosuppressed population prone to a variety of opportunistic infections.¹²⁸

Everolimus is a similar inhibitor of the mTOR pathway that has been used as an immunosuppressive agent in solid-organ transplantation and in treatment of renal cell cancer and neuroendocrine tumors. Several types of pulmonary toxicity have been described, including organizing pneumonia and the subacute onset of interstitial pneumonitis.¹²⁹ The interstitial pneumonitis has been reported in varying severity. In one report of interstitial lung disease while

receiving everolimus, four patients underwent BAL, which demonstrated lymphocytosis; two patients also had increased eosinophil counts.¹³⁰ Transbronchial biopsies from three of the patients demonstrated interstitial lymphocytic inflammation and septal thickening.¹³⁰ Treatment may involve observation in mild cases but can require discontinuation of the drug and initiation of glucocorticoids in severe cases.^{131,132} The use of glucocorticoids is of unclear benefit.

Temsirolimus is active against a variety of solid tumors, including endometrial cell carcinoma, breast cancer, and neuroendocrine tumors. It is FDA-approved for the treatment of advanced renal cell carcinoma. In a retrospective review of 22 patients treated with temsirolimus, eight patients (36%) developed pulmonary complications. Half of these patients were symptomatic. On radiographic studies, two different patterns of involvement were identified consisting of ground-glass opacities or alveolar consolidation. Pneumonitis has recurred in some cases with rechallenge.¹³³ Discontinuation of the drug is advised.^{134,135}

ANTIMICROBIAL AGENTS

NITROFURANTOIN

Acute Reaction

Nitrofurantoin pneumonitis may be one of the most common drug-induced pulmonary diseases.¹³⁶⁻¹³⁸ Acute pulmonary reactions are probably underestimated. The incidence has been estimated to be anywhere from 1 in 550 to 1 in 5400 individuals.¹³⁸ The mechanism of the acute nitrofurantoin reaction is unknown.

The typical reaction begins a few hours to several days after initiation of therapy. It appears to be much more common in women, perhaps due to the increased use of this drug in women. Fever is present in the majority of cases, dyspnea is almost always present, and cough is present in about two thirds of cases. Other incidental findings include leukocytosis and eosinophilia in one third and an elevation in sedimentation rate in nearly one half of cases. Imaging shows either an alveolar or an interstitial process or both. The reaction may be unilateral or asymmetrical and is generally most prominent at the bases. Pleural effusion has been found in one third of patients, most commonly unilaterally. Bronchospasm has been reported in a number of cases, but its incidence is unknown; it may happen in the absence of pulmonary parenchymal or pleural disease.¹³⁸

The treatment consists of discontinuing the medication and providing supportive care. It is not known whether corticosteroids accelerate the resolution, and there is probably no indication for their use. There is also no role for rechallenge to confirm the diagnosis. Nitrofurantoin-induced SLE with pleuropulmonary disease and positive antinuclear antibody has also been reported.

Chronic Reaction

There is no clinical overlap between the acute and chronic pulmonary reaction to nitrofurantoin. Chronic reactions are far less common than acute pulmonary reactions. In chronic reactions, fever and eosinophilia are much less common.¹³⁷⁻¹³⁹ The onset of dyspnea and cough is usually

insidious, beginning after 6 months to many years of continuous or intermittent use of nitrofurantoin. These reactions are more common in women.

Chest imaging shows a diffuse interstitial process.^{138,139} There is no associated bronchospasm or obstructive airway disease. Pulmonary function testing demonstrates a restrictive pattern. BAL usually shows a lymphocytic reaction. Histologic analysis of lung tissue shows inflammatory cells and fibrosis. Clinically, radiologically, and histologically, this condition often mimics other forms of interstitial lung disease, including usual interstitial pneumonia or nonspecific interstitial pneumonia patterns (eFig. 71-11).

The literature varies as to the utility of corticosteroids. Our experience is that they are almost always required for significant resolution. Others imply that the opacities resolve spontaneously on discontinuation of the medication.¹³⁹ Our policy is to observe the patient for 2 to 4 months after discontinuing nitrofurantoin and then repeating the imaging and pulmonary function studies. If there is no improvement, a trial of corticosteroids is given.¹⁴⁰

SULFASALAZINE

Sulfasalazine is an antimicrobial drug that has been used for many years for the treatment of inflammatory bowel disease.¹⁴¹ There appear to be two separate types of adverse pulmonary reactions: one is a pulmonary opacity with eosinophilia, and the other an organizing pneumonia pattern of pulmonary injury. After 1 to 8 months of continuous therapy, patients experience the onset of cough, dyspnea, and, in about half of cases, fever. The chest radiograph shows a variable pattern of lung opacities, ranging from upper lobe alveolar opacities to a diffuse interstitial process. More than half of the patients have significant blood eosinophilia. Resolution is seen within 1 week to 6 months after discontinuing the drug and, if necessary, adding corticosteroids. Sulfasalazine is metabolized to 5-aminosalicylic acid and sulfapyridine, both of which have been implicated in eosinophilic pneumonitis. In cases of suspected sulfasalazine-associated pulmonary disorders, it is important to keep in mind that inflammatory bowel disease has been associated with a variety of pulmonary abnormalities independent of sulfasalazine use. Inflammatory bowel disease has been independently linked to airway inflammation, interstitial lung disease including an organizing pneumonia pattern of pulmonary injury, neutrophilic necrotic pulmonary nodules, and serositis. Most of these disorders respond to corticosteroid therapy.

MISCELLANEOUS ANTIMICROBIAL DRUGS

There are many scattered reports of unusual reactions to various antimicrobial drugs. In view of the wide use of these agents, the incidence is extremely small. Many of these reactions appear to be pulmonary opacities with eosinophilia (eFig. 71-12). The polymyxin and aminoglycoside antibiotics are known to produce respiratory muscle weakness when they reach an excessive level in the blood.¹⁴² Antibiotics can reach toxic levels in the blood in patients to whom these drugs are given by direct instillation into the peritoneal or pleural space, in persons with renal failure, or in patients receiving them together with a muscle-relaxing

agent at the time of general anesthesia. These effects are reversible with physostigmine. The combined administration of amphotericin B with granulocytes may predispose some patients to transient deterioration in pulmonary function.¹⁴³

ILLICIT DRUGS

HEROIN

Although nitrofurantoin appears to be the prescribed drug with the most commonly reported adverse pulmonary effects, heroin pulmonary edema may be the most common drug-induced pulmonary disease worldwide. Hospitals in all major cities of the United States receive hundreds of patients with heroin pulmonary edema. Heroin is diacetylmorphine and, because of its increased lipid solubility, it crosses the blood-brain barrier much more readily than morphine. There are several postulated mechanisms of heroin-induced noncardiac pulmonary edema. These include a direct toxic effect on the alveolar-capillary membrane, leading to an increased permeability and extravasation of fluid into the alveolar spaces; a neurogenic response to central nervous system injury; an allergic or hypersensitivity reaction; and an acute hypoxic effect on the alveolar-capillary membrane in association with secondary increased permeability.

Heroin can cause pulmonary edema with the first intravenous use of the drug. It is believed that the effects of heroin are related to the dose. However, the exact dose is almost always unknown. Up to 40% of addicts hospitalized for acute drug overdose have acute pulmonary edema with severe hypoxemia and hypercapnia. The noncardiac pulmonary edema is indistinguishable at the outset from other forms of ARDS. The pulmonary capillary wedge pressure is usually within normal range. Typically, symptoms of dyspnea and somnolence begin within minutes of the intravenous "push," but reports of delayed onset of hours and even a few days have been published. The patient hypoventilates, becoming hypoxemic and hypercapnic. The pupils are small. Auscultation of the lungs discloses crackles. Imaging (see Fig. 62-4) typically shows changes of noncardiac pulmonary edema. Acidosis can be metabolic and respiratory.

Up to one half of these patients vomit and aspirate, which may complicate interpretation of the chest radiograph and later lead to secondary bacterial infection. Infection should be suspected if the pulmonary opacities do not clear within 24 to 48 hours of treatment. Other pulmonary abnormalities include septic emboli from infected thrombophlebitis or tricuspid endocarditis. Treatment consists of assisted ventilation using positive end-expiratory pressure, oxygen, and intravenous naloxone to reverse the respiratory depression. This is usually sufficient treatment for the noncardiac pulmonary edema, which will reverse with time. Corticosteroids are unnecessary. Because up to half of these patients have aspirated and have bacterial infections, appropriate use of antimicrobial drugs is indicated.

Bronchiectasis and necrotizing bronchitis in chronic heroin abusers have been reported. These may be more sequelae of recurrent gastric aspiration than the effects of

heroin, with or without pulmonary edema. Pulmonary function is abnormal in patients with pulmonary edema. Even after the radiographic clearance of the edema and the return of the lung volumes to normal, a reduction in the DL_{CO} may persist. In chronic abusers of heroin and other illicit intravenous drugs, pulmonary function abnormalities are more likely to be related to talc granulomatosis (see later) than to sequelae of a single acute injury.

METHADONE

Pulmonary sequelae similar to those associated with heroin have been reported with methadone and likely have similar mechanisms. Treatment is the same as for heroin-induced sequelae. Noncardiac pulmonary edema has been reported in cases of both oral and intravenous overdose of methadone.

METHYLPHENIDATE

Methylphenidate may have more serious adverse side effects than either heroin or cocaine.^{144,145} Methylphenidate can be abused either intravenously or orally. In one series of methylphenidate abuse, all 22 patients had chest pain and wheezing and most had abnormal pulmonary function tests and hemoptysis.¹⁴⁴ In another series, severe panlobular emphysema (eFig. 71-13) was found in 7 patients at autopsy.¹⁴⁵

COCAINE

Cocaine use remains a major problem throughout the world, and there are increasing reports of adverse pulmonary effects from both intravenous and inhalation use of the drug. These are over and above the known cardiac effects of cocaine, which produces left ventricular failure with pulmonary congestion and edema. The principal effects of cocaine are infection and aspiration, noncardiac pulmonary edema (eFig. 71-14), particulate embolization, talcosis, diffuse alveolar damage, diffuse alveolar hemorrhage (eFig. 71-15), intra-alveolar eosinophilic infiltration, lung mass with or without cavitation, and an organizing pneumonia pattern of lung injury (Table 71-3).^{146,147}

TALC GRANULOMATOSIS

Talc (magnesium silicate) and other agents, such as cellulose, are used as fillers in many medications intended for oral use. Addicts who abuse oral medications such as

meperidine, methadone, methylphenidate, amphetamines, and tripeleminamine often crush the tablets, mix them with various solutions, and inject them intravenously. This results in the insidious onset of granulomatous interstitial fibrosis, granulomatous pulmonary arterial occlusion, or both.¹⁴⁶⁻¹⁴⁸ In large series of consecutive autopsies done on addicts, depending on the type of addiction, the incidence of talc granulomatosis ranges from 15% to 80%.

Dyspnea is the major symptom, with cough in some patients; in more advanced stages of pulmonary hypertension, there may be exercise-induced syncope, right-sided heart failure, and even sudden death. Chest radiography may be normal in up to half of patients with proven talc granulomatosis. Pulmonary function studies characteristically show a low diffusing capacity before any other abnormalities are evident. Imaging in patients with injection granulomatosis may show diffuse micronodular densities varying in size between 1 and 3 mm (eFig. 71-16), which may mimic alveolar microlithiasis or hypersensitivity pneumonitis. Pulmonary opacities resulting from injection talcosis may show hyperattenuation at chest CT (eFig. 71-17). Therapy with corticosteroids provides little consistent improvement.

Histologically, the pulmonary tissue demonstrates granulomatous changes, with multinucleated giant cells, mononuclear inflammatory cells, lymphocytes, and fibrosis. Talc is detected by the presence of strongly birefringent crystals (using polarized light) within the granulomas (eFig. 71-18). BAL fluid shows an increased lymphocytosis and sometimes contains intracellular and free talc.

CARDIOVASCULAR DRUGS

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibitors are widely used for control of hypertension and in the management of congestive heart failure. Soon after their introduction, these agents were associated with nonproductive cough and more rarely with angioneurotic edema. Dry cough develops in 5% to 20% of patients on ACE inhibitors, being reported with captopril, enalapril, lisinopril, and virtually all other ACE inhibitors. The mechanism of ACE inhibitor-induced cough likely involves accumulation of kinins and substance P, which are degraded by ACE and other endopeptidases. The cough generally is reported in the first few weeks after beginning therapy but may not be appreciated for a number of months. ACE-induced cough is usually benign but can be quite annoying and causes the discontinuation of these agents in half of the patients affected. Exacerbation of bronchospasm has been associated with ACE inhibitors only on rare occasions. Fortunately, most patients can be switched to other classes of drugs. Rechallenge with a different ACE antagonist is not recommended as the cough will usually return. Cough generally abates within 4 days of discontinuation of the agent, providing confirmation of the diagnosis. Of note, selective angiotensin receptor antagonists have much lower incidence of dry cough compared with ACE inhibitors and may represent a therapeutic option for many patients.

Intra-alveolar eosinophilic infiltration
Lung mass with or without cavitation
Organizing pneumonia

ACE inhibitors cause angioedema much less frequently; this condition is reported in 0.1% to 0.2% of patients receiving ACE inhibitors. This complication usually arises within hours to, at most, 1 week after initiating therapy, and can be life-threatening. This reaction may be mediated by bradykinins but may also involve autoantibodies and complement system activation. Treatment is supportive and consists of airway protection. Although frequently used, epinephrine, antihistamines, and corticosteroid administration are of unclear value. The ACE inhibitor must be discontinued and future use avoided in these patients.

AMIODARONE

Amiodarone has significant benefit for ventricular and supraventricular dysrhythmias in patients who do not respond to most other antiarrhythmic agents. This drug is associated with a number of side effects, which include corneal microdeposits (in nearly 100% of the patients); peripheral neuropathy; liver dysfunction; thyroid dysfunction, including hypothyroidism and hyperthyroidism; and bluish pigmentation of the skin. However, the most serious side effect is an interstitial pneumonitis, which develops in up to 6% of patients and may be fatal.

The mechanism of amiodarone toxicity is unknown, but the toxicity is dose related and has distinctive histologic features. The histologic findings generally include foamy alveolar macrophages and type II pneumocytes containing lamellar inclusions. The incidence of pulmonary toxicity from amiodarone varies widely but probably averages 4% to 6% of those patients on the drug.^{11,149} The majority are men, but this may be related to increased use in men. Symptoms consist of insidious dyspnea, nonproductive cough, and occasionally a low-grade fever without chills, followed by subtle chest radiographic findings, which initially may be asymmetrical or even limited to the upper lobes. If the drug is continued, the process may diffusely involve the lungs with an interstitial or alveolar process. Pleural effusion is uncommon. Pleuritic chest pain exists in about 10% of patients. Crackles may be heard, but it is difficult to be certain whether these are due to pulmonary edema, because congestive heart failure is common in these patients. In about 20% of patients with amiodarone pneumonitis, the presentation will be acute, mimicking pneumonia (eFig. 71-19).

On laboratory studies, there is a normal to mildly elevated leukocyte count, generally no eosinophilia, and an elevated sedimentation rate, with little or no reactivity to antinuclear antibody. Pulmonary function studies disclose a decrease in the total lung capacity and DL_{CO} , as well as hypoxemia. There may be an increased predisposition to amiodarone pneumonitis if either pulmonary function or imaging findings are abnormal before administration of the drug begins.

The majority of the patients who develop amiodarone pneumonitis have been taking the drug for at least a month, and some for a few years. Most are receiving at least 400 mg/day. However, there have been a number of reports of amiodarone pneumonitis in patients taking as little as 200 mg/day. There are also reports of patients receiving 200 mg/day for months or even years and not developing amiodarone pneumonitis until the dose is boosted for better control

of the arrhythmia. Generally, the systemic side effects from amiodarone, such as peripheral neuropathy and liver dysfunction, correlate with the serum levels, but this is not necessarily the case with the pulmonary toxicity. Perhaps the greater phospholipid turnover in the lung explains the greater chance for lung toxicity from amiodarone. The diagnosis of amiodarone pneumonitis is one of exclusion.

Normally, amiodarone pneumonitis is thought to be primarily an interstitial or alveolar process (or both) sometimes mimicking eosinophilic pneumonitis with peripheral opacities (eFig. 71-20), but there are a number of reports of confluent lesions and other patterns (eFig. 71-21). Many of these lesions represent an organizing pneumonia injury pattern (see eFig. 71-23D).^{150,151} Chest CT imaging can further define these processes because amiodarone, being an iodinated compound, is radiopaque and, on a CT scan, the amiodarone pneumonitis lesions are denser than the surrounding soft tissue in the chest wall (Fig. 71-5, eFig. 71-22). This latter finding may help support the diagnosis.

Treatment consists of drug withdrawal and leads to a variety of responses. Some patients who were not treated with corticosteroids have died of pulmonary fibrosis and respiratory failure. Others have died in spite of being treated with corticosteroids. The majority respond to discontinuation of the drug and addition of corticosteroids (see eFigs. 71-19 and 71-21), which are usually required for a period of at least 2 and perhaps 6 months or longer. There are many case reports of patients who continued on amiodarone because it was the only drug that controlled their arrhythmia and who at the same time were given corticosteroids to suppress their pneumonic reaction.¹⁵²

Initially, it was believed that tissue confirmation was necessary to establish a diagnosis, although stopping the drug and adding corticosteroids may offer a presumptive diagnosis if the process clears. BAL produces variable results.¹¹ The presence of foamy macrophages in lavage fluid or on biopsy only confirms exposure to the drug; their presence alone

Figure 71-5 Amiodarone-induced lung disease. A chest CT scan showing confluent pulmonary masses (arrows) from amiodarone pneumonitis. Note that the masses are appreciably denser than the surrounding soft tissue in the chest wall in this CT scan obtained without contrast.

Radiation	

does not necessarily indicate amiodarone toxicity. Their absence does not exclude the diagnosis, however. Although not used frequently in recent years, a positive ^{67}Ga scan can be highly suggestive of an inflammatory pneumonitis rather than congestive heart failure. If the diagnosis has not been established, the clinician must decide whether to proceed with an open-lung biopsy to rule out other disease processes or to consider diminishing the dose or discontinuing the drug, or adding corticosteroids, or both. A lung biopsy usually reveals the foamy macrophages and epithelial cells, as well as variable inflammatory cell infiltration (eFig. 71-23). The histopathologic patterns of amiodarone-induced pulmonary injury vary, with the most common pattern of injury being a cellular interstitial pneumonia (see eFig. 71-23). However, some patients may exhibit an organizing pneumonia injury pattern (Table 71-4, see eFig. 71-23D). Reductions in sedimentation rate following discontinuation or reduction of amiodarone dosage may be of further value in establishing the diagnosis.

There are reports that patients on amiodarone can develop a postoperative ARDS, an injury that begins 18 to 72 hours after surgery. Several of these patients have died as a result.^{153,154} In a recent population-based study, amiodarone was responsible for approximately 2.7% of cases of acute lung injury.¹⁵⁴ It has been postulated that the high fraction of inspired oxygen given during the operation and the postoperative period contributes to this complication.

PROTAMINE

Protamine sulfate is used to reverse the anticoagulant effects of heparin following cardiovascular surgical procedures. Systemic hypotension is not uncommon following administration of this drug. However, there have been a number of cases of noncardiogenic pulmonary edema within minutes to 1 or 2 hours after the administration of the drug.¹⁵⁵ It is frequently associated with an anaphylactic reaction and bronchospasm, an increase in pulmonary artery pressure with normal wedge pressure, and hypotension. In at least half of the patients there is a history of previous use of protamine, either in a similar situation or as protamine zinc insulin. Skin testing can confirm the sensitization. Therapy is supportive, including reintubation if the patient has been extubated, assisted ventilation with high inspired oxygen concentrations, administration of high-dose corticosteroids, and treatment of hypotension with an α -adrenergic agonist. In patients whose skin test is positive to protamine or who have a history of reaction to protamine, intravenous hexadimethrine can be used to reverse the effects of heparin.

β -ADRENERGIC ANTAGONISTS

β -Adrenergic antagonists are among the most commonly prescribed drugs. β -Adrenergic receptors can be divided into excitatory β_1 -receptors, located in the heart, and inhibitory β_2 -receptors, located in the bronchi. The β -adrenergic blockers, or β -blockers, are competitive antagonists.

Propranolol was the first β -adrenergic antagonist introduced. It was quickly recognized that it had adverse effects on individuals with known obstructive lung disease. Studies have also demonstrated that propranolol increased airway resistance in normal persons and in asymptomatic asthmatic patients.¹⁵⁶ Thus this agent should be avoided in all patients with known obstructive lung disease, even those who are asymptomatic. The following β -adrenergic antagonists, presented in decreasing order of bronchoprovocation potential, are available for clinical use in the United States: propranolol, timolol, nadolol, metoprolol, atenolol, and labetalol.¹⁵⁷

Two features of β -adrenergic antagonists predict their potential for bronchoprovocation: their cardioselectivity and their intrinsic sympathomimetic activity. Generally, cardioselectivity is the more important of the two in avoiding bronchoconstriction; if the drug is cardioselective, it has little effect on the inhibitory β -receptors located in the bronchial walls. Propranolol, timolol, and nadolol have essentially no cardioselectivity and thus have a higher bronchoprovocation potential. Metoprolol has some cardioselectivity, and atenolol has considerable cardioselectivity, making atenolol one of the drugs of choice in an individual with obstructive airway disease who needs a β -adrenergic antagonist. The other mechanism important in avoiding bronchoconstriction with β -adrenergic antagonists is intrinsic sympathomimetic activity; pindolol has strong intrinsic sympathomimetic activity, accounting for its lower bronchoprovocation potential. As an exception to the rule, labetalol is unique in that it has the lowest bronchoprovocation potential despite not having cardioselectivity or intrinsic sympathomimetic activity. It does have combined α - and β -antagonist effects. Thus it is assumed that its α -adrenergic antagonist potential causes it to be bronchoprotective.

Thus, among the seven drugs listed, atenolol and then metoprolol and probably labetalol are the three that can be used with relative safety in persons with obstructive lung disease, if absolutely necessary. However, these should always be given in conjunction with an aerosolized β_2 -adrenergic agent. Calcium channel blockers may be a good alternative to β -blocking drugs, if indicated, because they also may have some bronchodilating capabilities.

The same findings have been described in asthmatic patients receiving timolol eye drops for glaucoma. There are many case reports of the adverse effects of topical ocular timolol, including a number of fatal cases of status asthmaticus.¹⁵⁸ Topically applied timolol is absorbed through the conjunctiva and bypasses the liver, resulting in a higher serum concentration than when given orally. A novel ocular β -adrenergic antagonist, betaxolol, has been shown to be safer in patients with known airway disease. There are scattered reports of β -blocker-associated interstitial pneumonitis.¹⁵⁹ Propafenone is an additional membrane-stabilizing antiarrhythmic agent that is structurally similar to propranolol and has the potential to aggravate bronchospasm.¹⁶⁰

TOCAINIDE AND FLECAINIDE

Tocainide is used in the treatment of refractory ventricular arrhythmias. There are more than 100 known cases of acute interstitial pneumonitis beginning 3 weeks to several months after initiation of therapy.¹⁶¹ The response to discontinuing the drug is good; corticosteroids may be necessary in some cases. Flecainide, another antiarrhythmic agent, has been reported to be associated with the ARDS and an interstitial lymphocytic pneumonitis.^{35,162}

ANTI-INFLAMMATORY AGENTS

ASPIRIN

Anti-inflammatory agents are among the most commonly used drugs, and many have pulmonary side effects. Aspirin is the most commonly used drug in the world. In the United States, there are more than 200 proprietary drugs that contain aspirin. It is estimated that up to 5% of asthmatics are sensitive to aspirin; ingestion may cause fatal aggravation of bronchospasm.¹⁶³ The exact cause of aspirin-sensitive asthma is unknown. One theory is that, by inhibiting cyclooxygenase, aspirin and similar compounds prevent the generation of cyclooxygenase products such as the prostaglandins. If certain individuals are reliant on the bronchodilator activity of prostaglandins such as prostaglandin E₂, their inhibition could cause bronchospasm. The aspirin-asthma triad consists of asthma, rhinitis, and nasal polyposis. Almost always there are other associated side effects, such as cutaneous rashes and gastrointestinal symptoms. These adverse reactions are not dose related because they can develop with very small doses. Salicylates can induce noncardiac pulmonary edema in cases of overdose when the serum salicylate level is greater than 40 mg/dL.

OTHER NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Most of the nonsteroidal anti-inflammatory agents can produce the same side effects as aspirin, including aggravation of asthma, noncardiac pulmonary edema, drug-induced SLE, and pulmonary opacities with eosinophilia. Naproxen may be more commonly associated with an opacity and eosinophilia than are the other agents.¹⁶⁴ A few agents can cause hypervolemia and, in turn, pulmonary edema through the mechanism of increased sodium retention through the kidneys.

Penicillamine

Penicillamine is used to treat Wilson disease, rheumatoid arthritis, and cystinuria and has been associated with pulmonary toxicity. There are three possible pulmonary complications with the use of penicillamine with no apparent overlap: penicillamine-induced SLE, bronchiolitis obliterans, and Goodpasture syndrome. Penicillamine-induced SLE may induce pneumonitis, alveolitis, and sometimes pleural effusion. Penicillamine-associated bronchiolitis obliterans is probably underestimated in its incidence and severity. Corticosteroids have little benefit in treating this

condition, which usually presents in an advanced state. There have also been several case reports of penicillamine-associated Goodpasture syndrome with diffuse alveolar hemorrhage.¹⁶⁵ If recognized early enough, appropriate therapy with hemodialysis, plasmapheresis, and immunosuppression may prevent a serious outcome.

Leflunomide

Several new agents have in recent years been found to be efficacious in the treatment of inflammatory conditions with a considerably improved safety profile when compared with the previous regimens used. Leflunomide received its FDA approval in 1998 and is currently used to treat rheumatoid arthritis and psoriatic arthritis. It is a pyrimidine synthesis inhibitor, which exerts mainly an immunomodulating effect, although it was also found to exert significant anti-inflammatory effects. Its main described adverse effect is liver toxicity, and it may act synergistically with methotrexate. Several patterns of lung injury have been observed with leflunomide, mostly consisting of hypersensitivity reactions. In a postmarketing surveillance study, significant lung toxicity was identified in 61 of 5053 patients, with 24 patient deaths directly related to the pulmonary complications. Preexisting lung disease and, to a lesser degree, loading dose, a smoking history, and low body weight have been identified as independent risk factors. A case-control study also showed a higher incidence of lung toxicity in those with prior lung disease but suggested that was because higher-risk patients were more likely to receive leflunomide.¹⁶⁶ True hypersensitivity pneumonias have also been reported in case series, as defined by interstitial opacities associated with ill-defined granulomas.¹⁶⁷ Nonspecific opacities with or without eosinophilia have also been reported. Diffuse alveolar hemorrhage and pulmonary alveolar proteinosis are rarely encountered. Cholestyramine wash-out therapy has been shown to treat leflunomide-induced pneumonitis; oral cholestyramine binds the drug and its metabolites, removes them from the body, and greatly shortens their otherwise long half-life.¹⁶⁸

BIOLOGIC AGENTS

These agents have truly revolutionized the management of a number of chronic inflammatory conditions such as rheumatoid arthritis, inflammatory bowel disease, and psoriasis. *Antitumor necrosis factor- α* (TNF- α) medications such as infliximab (a chimeric monoclonal antibody targeting TNF- α), etanercept (a soluble TNF- α receptor), or adalimumab (recombinant monoclonal antibody targeting TNF- α) have been used with various success in these conditions by directly interfering with the first steps of the inflammatory cascade. Not unexpectedly, infections are a major complication of these treatments—tuberculosis, in particular, may easily reactivate in a context of impaired T-cell immunity. Tuberculosis skin tests or interferon-gamma release assays for *Mycobacterium tuberculosis* are mandatory before initiation of treatment. Extrapulmonary manifestations seem relatively common (40 of 70 patients in an initial report), with most cases reported in areas with a low incidence of tuberculosis, perhaps because these drugs tend to be used in more developed countries. Interestingly, other

Figure 71-6 Mediastinal lipomatosis in response to corticosteroids. **A**, Chest radiograph before systemic corticosteroid administration. **B**, Chest radiograph after corticosteroid administration shows widened mediastinum (arrows). **C**, Chest CT scan shows mediastinal lipomatosis, with radiographic fat density (arrows) surrounding the great vessels and tracheal shadows.

opportunistic infections, including fungal lung infections, although described, are less of a concern with these agents. Multiple patterns of lung injury have been described with infliximab, including acute hypersensitivity reactions with or without eosinophilia, nonspecific interstitial pneumonitis, *de novo* usual interstitial pneumonia (UIP), or exacerbation of rheumatoid arthritis–associated UIP and vasculitis.¹⁶⁹ Two other anti-TNF- α medications, adalimumab (eFig. 71-24) and etanercept, have also been described in association with pulmonary fibrosis, but these associations are relatively weak and mainly based on isolated case reports.^{170,171} Etanercept has also been associated with pulmonary granulomatous inflammation.¹⁷²

LEUKOTRIENE ANTAGONISTS

The potent antiasthma agents, zafirlukast, montelukast, and pranlukast, have been associated with eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome).¹⁷³⁻¹⁷⁵ A number of cases have been described with patients exhibiting pulmonary opacities, cardiomyopathy, and eosinophilia while receiving zafirlukast. A systematic review of the cases reported in the literature identified 62 cases of eosinophilic granulomatosis with polyangiitis after initiation of leukotriene antagonists.¹⁷⁵ Although some of the cases may have had preexisting eosinophilic granulomatosis with polyangiitis, many demonstrated a temporal relationship to the leukotriene antagonist.¹⁷⁵ As a leukotriene antagonist is added to an asthmatic treatment regimen, corticosteroids are frequently tapered, suggesting that some of the effects of adding leukotriene antagonists are actually effects of tapering corticosteroids. However, a small number of these patients were not receiving oral or inhaled corticosteroid at the time the medication was added. Eosinophilic granulomatosis with polyangiitis developed 6 to 18 months after initiation of the leukotriene antagonist. Remission of the signs and symptoms were noted with removal of the leukotriene antagonist with or without escalation of treatment. It is currently unknown whether these medications

actually trigger these reactions or whether they are unmasking a preexistent infiltrative eosinophilic disorder.¹⁷⁵ In either event, the pulmonary reaction responds to discontinuation of the leukotriene antagonist and reinstitution of corticosteroids.

CORTICOSTEROIDS

Corticosteroids given in immunosuppressive doses are well known for predisposing to the development of opportunistic infections. A most unusual adverse effect of corticosteroids is mediastinal lipomatosis, the deposition of mediastinal fat, which produces a widening of the mediastinum that mimics lymphadenopathy or other neoplasms (Fig. 71-6). Clinically, these patients have a cushingoid appearance, with rounded facies and a “buffalo hump.” The same kind of fat that deposits in the buffalo hump can deposit in the mediastinum. The chest radiograph does not show the lumpiness usually expected with adenopathy. Chest CT can usually make this diagnosis by establishing fat density throughout the mediastinal mass (see Fig. 71-6). Mediastinal lipomatosis does not necessitate tapering corticosteroids because the fat does not compromise vital structures.

DRUG-INDUCED SYSTEMIC LUPUS ERYTHEMATOSUS

Of more than 50 drugs associated with SLE, only 5 regularly induce antinuclear antibodies in patients taking them: hydralazine, procainamide, isoniazid, phenytoin, and penicillamine and only a small percentage of the patients on these drugs develop the clinical lupus-like syndrome. It is thought that patients who develop antinuclear antibodies to these drugs are *slow acetylators*, with a slower rate of metabolism of the offending drug. Symptoms almost always begin insidiously after the patient has been taking the drug for many months or even years. Systemic signs and

symptoms of polyarthralgia, myalgia, fever, pleurisy, and cutaneous lesions are common. However, renal disease is uncommon, possibly because complement is not as often involved in the drug-induced form of SLE compared with the spontaneous type.

The antinuclear antibody assay is positive in all patients with drug-induced SLE. However, the test for antinative (anti-double-stranded) DNA is negative. The complement level may or may not be abnormal. A Coombs test is positive in about one third of patients. An elevated erythrocyte sedimentation rate and hypergammaglobulinemia are common nonspecific findings.

The chest radiographic findings of the drug-induced form of the disease are indistinguishable from spontaneous-onset SLE and include pleural effusions in one third of patients, basilar opacities, pneumonitis with atelectasis, and apparent cardiomegaly from pericardial effusion. Pleural fluid glucose is normal or at least correlates with the blood glucose levels.

The symptoms usually resolve once the drug is discontinued. However, occasionally it is necessary to add corticosteroids for more rapid resolution of disabling symptoms. If the offending drug cannot be discontinued for clinical reasons, the lowest dose should be used, along with the addition of corticosteroids.

INHALANTS

OIL

Aspirated oil can produce a variety of pulmonary diseases, ranging from an asymptomatic solitary nodule to diffuse disease with severe respiratory insufficiency.^{176,177} Most commonly, however, the disease presents in an asymptomatic individual with an incidental finding of an abnormal chest radiograph that mimics a more serious process such as bronchogenic carcinoma. Because patients rarely consider oily nose drops, oily eye lubricants, and mineral oil as medications, they rarely volunteer that they are taking oil-containing medications.

There are three types of oil: mineral oils, neutral oils, and animal fats. Mineral oils are the most commonly aspirated oils. Oily droplets are taken up by macrophages that eventually die and release the oil, which in turn inhibits ciliary activity. Thus the oil is not expectorated and the cycle is repeated. Eventually, the oil incites a fibrotic or granulomatous reaction. Neutral or vegetable oils (e.g., olive or castor oil) do not elicit a local reaction and can be removed by expectoration. Animal fats (e.g., milk, butter) are rapidly hydrolyzed, with the liberated fatty acids producing tissue necrosis and subsequent fibrosis. The diagnosis can be established with the demonstration of oil in the lung tissue. CT and magnetic resonance imaging have been used in diagnosing lipid-induced opacities.¹⁷⁶ The "CT angiogram" sign, defined by the ability to distinguish the pulmonary vasculature within an area of consolidation, was once thought to be fairly specific for lipid pneumonitis but may be seen in a variety of unrelated conditions. Treatment involves the discontinuation of the oil-containing medication. With discontinuation, progression is unlikely.

OXYGEN

Exposure to high concentrations of oxygen may contribute to or aggravate the ARDS. There are two theories as to the mechanism of oxygen-induced pulmonary disease. The first is that a high fraction of inspired oxygen induces formation and release of free oxidant radicals. These short-lived molecules damage DNA, destroy lipid membranes, and inactivate intracellular enzymes.¹⁷⁸ The other theory is that hyperoxia produces a direct injury to endothelial cells and type I epithelial cells, which results in alveolar-capillary leak.¹⁷⁹

Studies in volunteers breathing 100% oxygen for 6 to 48 hours produced variable effects, but some developed a tracheobronchitis, with symptoms of substernal burning, chest tightness, and nonproductive cough. It also produced a reduction in vital capacity and DL_{CO} . The development of tolerance to hyperoxia appears to be related to the ability of the individual to increase the production of antioxidants, a mechanism that may be determined genetically.

The sequelae of oxygen toxicity are separable into two phases, the acute, or exudative, phase and the subacute proliferative phase; however, there is considerable overlap between the two phases, with the proliferative phase beginning after the fourth to seventh day. The exudative phase begins within 48 to 72 hours, depending on the fraction of inspired oxygen, and is associated with perivascular, interstitial, and alveolar edema with atelectasis, as well as alveolar hemorrhage. This phase appears to be reversible.

The proliferative phase is characterized by progressive resorption of exudates and hyperplasia of type II cells. This is followed by the deposition of collagen and elastin in the interstitium and hyaline membrane deposition. This is usually an irreversible phase. Clinically, hypoxemia and diminished compliance progress, requiring a greater fraction of inspired oxygen and assisted ventilation, further aggravating the problem. Imaging shows an alveolar-interstitial pattern in an irregular distribution, with evidence of moderate loss of volume from patchy atelectasis.

There is no clinical way of diagnosing oxygen toxicity. A lung biopsy specimen may show changes consistent with oxygen toxicity, but the primary value of the biopsy is to exclude other causes of lung injury. Keeping the arterial PO_2 less than 80 mm Hg or the inspired fraction of oxygen below 0.40 to 0.50 minimizes the likelihood of oxygen toxicity. Barotrauma and ventilator-induced injury may accompany and be indistinguishable from oxygen toxicity.

MISCELLANEOUS DRUGS/AGENTS

RADIOGRAPHIC CONTRAST MEDIUM-INDUCED LEUKOSTASIS

The symptoms and signs produced by complement-induced granulocyte aggregation associated with radiographic contrast media are frequently attributed to an allergic reaction and may cause noncardiac pulmonary edema. Anaphylaxis as a cause can be eliminated by the absence of urticaria or other rash, and by the absence of significant laryngeal edema or bronchospasm. Histologic examination of the lungs demonstrates aggregates of granulocytes obstructing

microscopic pulmonary arterioles and capillaries. These findings can be overlooked if not carefully sought or if the autopsy or examination of lung tissue is not done within a few hours of the reaction.

Clinically, the onset of symptoms of dyspnea and hypoxemia begins within a few minutes to an hour of the injection of the radiographic contrast medium. There is not necessarily a history of an allergic reaction to iodine. Treatment is supportive and includes a trial of high-dose corticosteroids, although this may be ineffective.

The activation of complement and, in turn, the generation of C5a stimulates granulocytes to aggregate and to adhere to endothelium, releasing proteases and toxic oxygen compounds. These, in turn, produce endothelial damage and capillary leakage. One study found high postmortem plasma histamine levels, which were thought to represent mast cell activation.¹⁸²

TOCOLYTIC-INDUCED PULMONARY EDEMA

Tocolytics are agents that have been widely used in the treatment of premature labor. The most commonly used drugs are terbutaline, albuterol, ritodrine, and other β -mimetic drugs. There are many reports of these agents inducing pulmonary edema in otherwise healthy women. The incidence varies from 0.5% to 5%. Predisposing factors include the use of corticosteroids, twin gestation, fluid overload (particularly with saline), and anemia. The β -mimetic drugs typically stimulate β_2 -adrenergic receptors, increase the maternal pulse rate and the cardiac output, and produce peripheral vasodilation. Hemodilution can be detected by a drop in the hemoglobin, hematocrit, and albumin. The blood pressure may drop as a result of the peripheral vasodilation.

A typical clinical scenario is as follows. In spite of the tocolytic agent, labor continues; the tocolytic agent is then stopped, and corticosteroids are added to accelerate fetal lung maturation. With the discontinuation of the tocolytic, the vasodilated vessels return to normal tone. During delivery, uterine contractions lead to autotransfusion. The increased venous tone and the increased blood volume can then lead to pulmonary edema, usually in the postpartum period.

There are conflicting reports of the wedge pressure ranging from normal to elevated. In one study, patients with an elevated wedge pressure had normal left ventricular function by echocardiography. At this point, it is uncertain whether the pulmonary edema is truly cardiac or noncardiac in origin.

The treatment is oxygen and diuresis. In certain cases, consideration has been given to resuming the tocolytic agent to recreate the previous peripheral vasodilation. Corticosteroids aggravate the situation by their mineralocorticoid effect, which promotes fluid retention. The differential diagnosis includes aspiration of gastric contents, left-sided heart failure, amniotic fluid embolism, and overtransfusion.

HYDROCHLOROTHIAZIDE

More than 40 reported cases of acute onset of diffuse pulmonary opacities are associated with hydrochlorothiazide.¹⁸⁰

It may begin with the first dose or days later; 90% of cases have been reported in women who take the drug intermittently rather than daily, presumably for fluid retention. Symptoms consist of fairly rapid onset of dyspnea that clears 48 to 72 hours after discontinuing the drug. A low-grade fever may be present. Eosinophilia and antinuclear antibodies are not present. The chest radiograph shows diffuse bilateral alveolar-interstitial opacities. In the few cases studied, the pulmonary capillary wedge pressure was normal.

METHYSERGIDE, BROMOCRIPTINE, AND CABERGOLINE

Methysergide, bromocriptine, and cabergoline are structurally similar and produce similar pleuropulmonary reactions. Methysergide is now rarely used to treat vascular headaches because there are better alternative drugs. Bromocriptine and cabergoline are used for the treatment of Parkinson disease. The pleuropulmonary disease produced by both of these agents has an insidious onset. The predominant feature is pleural thickening and effusion, which is reversible by discontinuing the medication. Effusions are rarely large, are not commonly associated with pleuritic pain, and may show lymphocytosis.¹⁸¹

DEXTRAN

Hyskon is a low-molecular-weight dextran that is capable of producing a noncardiac pulmonary edema.¹⁸² It is used principally in hysteroscopic surgery, most often for improving fertility, during which the endometrial cavity is distended with approximately 500 mL of low-molecular-weight dextran. The incidence of noncardiac pulmonary edema increases significantly if more than 500 mL is used, endometrial surfaces are excessively irritated, or the procedure lasts more than 45 minutes. In addition to noncardiac pulmonary edema, coagulopathy can also develop.

AMPHETAMINERGIC AGENTS

In the 1960s, excess cases of pulmonary hypertension were associated with the potent anorexigen aminorex fumarate. More recently, pulmonary hypertension has been associated with dexfenfluramine, fenfluramine, and phenteramine.¹⁸³ Valvular heart disease has also been associated with these agents.¹⁸⁴ Although these agents were removed from the market in 2004, a careful drug history must be taken to exclude this possibility in patients presenting with dyspnea, cardiovascular symptoms, or heart murmurs because manifestations typically persist despite discontinuation of the drugs. A retrospective study on 340 patients with pulmonary hypertension identified a history of stimulant use in 29% of them, including methamphetamine, amphetamine, and cocaine, emphasizing the importance of seeking this part of history that may not be easily volunteered by the patients.

ESOPHAGEAL VARICEAL SCLEROTHERAPY

Esophageal variceal sclerotherapy with either sodium morrhuate, sodium tetradecyl sulfate, or ethanolamine oleate

can lead to multiple abnormalities. Typically about 1 mL of one of these substances is injected into or around the varices, and up to 15 to 20 injections are made during a single procedure. Chest radiographs performed shortly after the procedure were abnormal in 85% of the cases at the Mayo Clinic, but this was rarely of clinical significance.¹⁸⁵ Pleural effusion was seen in about 25% of patients, mediastinal widening in 33%, atelectasis in 12%, and pulmonary opacities in 9%. Fever, chest pain, and difficulty in swallowing were common after the procedure but were rarely serious.

In the literature, pleural effusion has been described in up to 50% of the patients; most of these patients were asymptomatic.¹⁸⁵ Effusions were more common when a large volume of fluid was injected and the volume per site was increased. Serious complications such as mediastinitis or frank esophageal rupture are rare but should be suspected if the fever persists for more than 24 hours, the pleural effusion is large, or chest pain persists. ARDS happens in less than 1% of the patients undergoing sclerotherapy.

PHENYTOIN

There has been much confusion in the literature as to whether or not phenytoin produces parenchymal pulmonary disease and mediastinal adenopathy. Reports in the affirmative have been followed by a more detailed patient study refuting the possibility of pulmonary parenchymal disease.^{186,187} The only two phenytoin-induced pulmonary diseases are drug-induced SLE and a few rare cases of hypersensitivity pneumonitis that show a predominance of lymphocytes found in the BAL fluid or biopsied tissue. The fact that phenytoin is one of the more commonly used drugs over extremely long periods of time and that it has not shown an obvious relationship for the induction of significant pulmonary disease makes it unlikely that there is a true relationship of any consequence.

DANTROLENE

Dantrolene is a long-acting skeletal muscle relaxant used in treating patients with spastic neurologic disorders.¹⁸⁸ There have been several case reports of chronic pleural effusion or pericarditis, or both, associated with this drug. Peripheral blood eosinophilia was seen in some patients who were taking dantrolene.

Key Points

- The frequency of drug-induced pulmonary toxicity may be underestimated because the diagnosis is one of exclusion in the vast majority of cases. Clinicians must maintain a high index of suspicion that unexplained pulmonary disease may be caused by medications.
- Most associations are based on anecdotal reports and circumstantial evidence.
- Potential mechanisms of lung injury include (1) oxidative injury, (2) direct cytotoxic effect, (3) accumulation of phospholipids, and (4) immune-mediated injury.
- Chemotherapy-induced lung toxicity should always be considered in the differential diagnosis of diffuse lung opacities because virtually all histopathologic presentations have been described.
- Even in situations in which cumulative toxicity is an issue, screening via serial imaging or physiologic studies is rarely helpful.
- Most drug-induced pulmonary reactions are reversible if the drug is stopped. If necessary, additional measures such as judicious use of corticosteroids may be helpful.
- Rechallenging the patient with the suspected drug is often dangerous and generally not indicated.
- If there is a question of whether or not a medication may be the cause of a particular pulmonary abnormality, one option is to call the medical director of the drug manufacturer, listed in the *Physicians' Desk Reference*. In addition, a useful website can be accessed at <http://www.pneumotox.com>.

eFIGURE IMAGE GALLERY

Figure 71-1 Bleomycin-induced lung injury; hypersensitivity reaction. Anterior (A) and posterior (B) planar ⁶⁸Ga scintigraphic images in a patient with Hodgkin lymphoma treated with bleomycin shows increased uptake in the lungs (arrows) in a symmetric, bilateral distribution. C–F, Axial chest CT obtained at the same time as the nuclear study (A and B) shows little evidence of an infiltrative abnormality on inspiratory images (C and D). On expiratory imaging, areas of decreased lung attenuation (E and F, arrowheads) are evident, representing air trapping and suggesting a small airway obstructive process. This pattern suggests bronchiolitis obliterans but can rarely be seen with hypersensitivity reactions. G and H, Axial chest CT obtained 2 weeks following (C–F) shows interval development of multifocal, bilateral areas of ground-glass opacity and reticulation; this pattern is consistent with an acute lung injury pattern, although the presence of the small airway obstruction, as shown on the initial CT (C–F), suggests a combined infiltrative and obstructive disorder, which is typical of a hypersensitivity reaction. Evaluation for infection and pulmonary hemorrhage was unrevealing. I and J, Axial chest CT following withdrawal of bleomycin, obtained 4 months following (C–F), shows clearing of the infiltrative lung opacity with minimal anterior lung scarring remaining. (Courtesy Michael Gotway, MD.)

eFigure 71-2 Histopathologic patterns of bleomycin-induced pulmonary injury. **A**, Diffuse alveolar damage from bleomycin toxicity. **B**, Reactive type II cells and organizing pneumonia (*op*) are commonly found. (From Cheung Y, Graziano P, Leslie KO: Acute lung injury. In Leslie KO, Wick MR, editors: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, pp 117–137, Fig. 5-28.)

eFigure 71-3 Diffuse alveolar damage from busulfan toxicity. **A**, Busulfan can produce diffuse injury characterized by the presence of prominently atypical type II cells. In this case, prominent interstitial organization with edematous fibroblastic proliferation is seen (*fp*), and hyaline membranes are evident. **B**, Reactive type II cells may appear alarmingly atypical (*arrow*). (From Cheung Y, Graziano P, Leslie KO: Acute lung injury. In Leslie KO, Wick MR, editors: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, pp 117–137, Fig. 5-29.)

eFigure 71-4 Methotrexate-induced lung injury; non-specific interstitial pneumonia pattern. A–D, Axial chest CT in a patient receiving methotrexate shows bilateral basal and peripheral predominant linear and reticular abnormalities associated with architectural distortion and mild traction bronchiectasis; the pattern resembles fibrotic nonspecific interstitial pneumonia. (Courtesy Michael Gotway, MD.)

eFigure 71-5 Diffuse alveolar damage (DAD) from methotrexate toxicity. A, Methotrexate produces small, poorly formed granulomas in subacute and chronic manifestations of lung toxicity. B, Early aggregations of macrophages may be seen resembling poorly formed granulomas in cases in which DAD is the manifestation of injury, but these are not required for the diagnosis (*arrow*). (From Cheung Y, Graziano P, Leslie KO: Acute lung injury. In Leslie KO, Wick MR, editors: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, pp 117–137, Fig. 5-31.)

eFigure 71-6 Paclitaxel-induced pulmonary injury. **A** and **B**, Axial chest CT in a patient with non-small cell lung carcinoma at the onset of paclitaxel therapy. **C** and **D**, Axial chest CT performed 2 weeks following initiation of paclitaxel therapy shows interval development of multifocal ground-glass opacity associated with reticulation. No evidence of infection or pulmonary hemorrhage could be found. The CT appearance is consistent with an acute lung injury pattern. (Courtesy Michael Gotway, MD.)

eFigure 71-7 All-trans retinoic acid (ATRA) syndrome in a patient treated for acute promyelocytic leukemia: chest radiographic findings. **A**, Frontal chest radiograph performed shortly following initiation of therapy, when the patient developed renal insufficiency and peripheral edema, shows multifocal bilateral opacities consistent with an acute lung injury, or “capillary leak,” pattern. **B**, Frontal chest radiograph following withdrawal of therapy and corticosteroid treatment shows resolution of findings. (Courtesy Michael Gotway, MD.)

eFigure 71-8 All-trans retinoic acid (ATRA) syndrome in a patient treated for acute promyelocytic leukemia: chest CT findings. A–D, Axial chest CT displayed in lung windows shows multifocal, bilateral areas of nodular ground-glass opacity resembling pulmonary hemorrhage, although no hemorrhage was found at bronchoscopy. The pattern is nonspecific but consistent with acute lung injury. The abnormalities resolved following cessation of all-trans retinoic acid therapy and corticosteroid treatment, and no infection was ever found. (Courtesy Michael Gotway, MD.)

eFigure 71-9 Interferon-induced sarcoid-like reaction. A–E, Axial chest CT in a patient with renal cell carcinoma treated with interferon-alfa shows multifocal, bilateral, patchy nodules (arrows) distributed along the bronchovascular bundles and fissural surfaces, typical of the appearance of sarcoidosis. No infectious etiology was found, and the findings worsened on repeat evaluation. F–J, Axial chest CT performed following withdrawal of interferon-alfa therapy shows resolution of the small nodules. (Courtesy Michael Gotway, MD.)

eFigure 71-10 Sirolimus-induced interstitial pneumonitis in a lung transplant recipient. A–D, Axial chest CT shows poorly defined, faintly nodular areas of ground-glass opacity (*arrowheads*) in the mid and upper lungs bilaterally. Extensive evaluation revealed no evidence of infection or hemorrhage, and the abnormalities resolved following withdrawal of sirolimus therapy. (Courtesy Michael Gotway, MD.)

eFigure 71-11 Nitrofurantoin-induced interstitial pneumonitis. Axial chest CT in a patient undergoing nitrofurantoin therapy shows bilateral, patchy, subpleural ground-glass opacity and reticulation (*arrows*) consistent with a nonspecific interstitial pneumonia lung injury pattern. (Courtesy Michael Gotway, MD.)

eFigure 71-12 Antibiotic-induced eosinophilic pneumonia lung injury pattern. **A**, Frontal chest radiograph in a patient receiving daptomycin shows bilateral, peripheral lung consolidation. **B–G**, Axial chest CT performed shortly following the chest radiograph shown in (**A**) reveals multifocal, bilateral, noticeably peripherally distributed areas of ground-glass opacity, consolidation, and reticulation (*arrowheads*). Bronchoscopy demonstrated pulmonary eosinophilia, without hemorrhage, and no evidence of infection was found. **H**, Frontal chest radiograph performed following discontinuation of daptomycin shows complete resolution of the pulmonary abnormalities. (Courtesy Michael Gotway, MD.)

eFigure 71-13 Panlobular emphysema in a patient abusing methylphenidate. **A**, Frontal chest radiograph in a 40-year-old woman with respiratory failure, known to abuse methylphenidate intravenously, shows enormous lung volumes. Note diaphragmatic flattening. **B**, Axial chest CT through the lung bases shows diffuse low attenuation and simplification of pulmonary architecture, consistent with panlobular emphysema. (Courtesy Michael Gotway, MD.)

eFigure 71-14 Noncardiogenic edema following cocaine inhalation. Axial chest CT performed in a patient who developed severe shortness of breath and cough following crack inhalation shows multifocal bilateral ground-glass opacity with peripheral sparing. No evidence of infection was noted. (Courtesy Michael Gotway, MD.)

eFigure 71-15 Pulmonary hemorrhage following cocaine inhalation. **A**, Axial chest CT performed in a patient complaining of shortness of breath and cough following crack inhalation shows patchy right lower lobe ground-glass opacity with interlobular septal thickening, consistent with hemorrhage; the latter was confirmed at bronchoscopy. **B**, Repeat axial chest CT 3 weeks following (**A**) shows clearing of the right lower lobe pulmonary hemorrhage. (Courtesy Michael Gotway, MD.)

eFigure 71-16 Injection cellulose granulomatosis in a patient injecting Vicodin tablets intravenously. **A–D**, Axial chest CT in an injection drug user shows numerous, diffusely distributed, bilateral ground-glass opacity nodules; the appearance closely resembles subacute hypersensitivity pneumonitis. Surgical lung biopsy showed a perivascular foreign body giant cell reaction with granulomas and polarizable refractive crystals consistent with cellulose. (Courtesy Michael Gotway, MD.)

eFigure 71-17 Injection talcosis. Axial chest CT displayed in soft tissue windows performed on an intravenous drug abuser shows bilateral mass-like opacities consistent with injection talc granulomatosis. (Courtesy Michael Gotway, MD.)

eFigure 71-18 Intravenous drug abuse-induced particulate foreign body reaction. **A**, Normal light microscopy appearance. **B**, Polarized light. A perivascular interstitial foreign body-type granulomatous reaction is associated with prominent vascular changes, as seen here. (From Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, pp 117–137, Fig. 7-73.)

eFigure 71-19 Acute amiodarone pulmonary toxicity. **A**, Frontal chest radiograph performed in a patient with supraventricular tachycardia recently loaded with amiodarone shows right lower lung opacity thought to reflect pneumonia. The patient was treated presumptively for pneumonia with broad-spectrum antibiotics. **B**, Frontal chest radiograph performed several days following **(A)** shows slight improvement in right lower lung opacity, but new right upper lobe opacity is now present. **C**, Follow-up frontal chest radiograph shows progression of the right lung abnormalities despite a normal intravascular volume and broad-spectrum antibiotic therapy. **D–G**, Axial chest CT displayed in lung windows shows multifocal, bilateral ground-glass opacities associated with fine reticulation and subpleural right lower lobe consolidation, but no features to suggest fibrosis. The findings are consistent with an alveolitis or hemorrhage but are nonspecific. **H**, Follow-up frontal chest radiograph shows continued worsening of bilateral lung opacities. **I**, Frontal chest radiograph performed several days following discontinuation of amiodarone shows significant improvement in bilateral lung opacities. (Courtesy Michael Gotway, MD.)

eFigure 71-20 Amiodarone pulmonary toxicity: nonspecific interstitial pneumonia pattern. **A** and **B**, Axial chest CT displayed in lung windows performed for a patient receiving chronic amiodarone therapy shows bilateral, subpleural fine intralobular interstitial thickening and ground-glass opacity; the appearance resembles a nonspecific interstitial pneumonia lung injury pattern. (Courtesy Michael Gotway, MD.)

eFigure 71-21 Amiodarone pulmonary toxicity: nodular organizing pneumonia pattern. **A** and **B**, Axial chest CT displayed in lung windows performed for a patient receiving chronic amiodarone therapy shows right lung nodules (*arrows*) associated with air bronchograms; one nodule shows ground-glass opacity surrounded by consolidation (**B**, *arrowhead*), consistent with the "reverse ground-glass halo" sign, or "atoll" sign, suggestive of organizing pneumonia. **C** and **D**, Axial chest CT performed following discontinuation of amiodarone therapy and implementation of corticosteroid treatment shows near complete resolution of the nodules. (Courtesy Michael Gotway, MD.)

eFigure 71-22 Amiodarone exposure: high attenuation lung consolidation. **A**, Axial chest CT performed in a patient taking amiodarone for an atrial arrhythmia shows high attenuation right lower lobe consolidation (*), consistent with amiodarone exposure. **B**, Axial chest CT through the upper abdomen shows increased attenuation of the liver parenchyma (L) relative to the spleen (S), also consistent with amiodarone exposure. (Courtesy Michael Gotway, MD.)

eFigure 71-23 Amiodarone toxicity. **A**, Scanning magnification of amiodarone-induced diffuse alveolar injury. **B**, The finely vacuolated macrophages in type II cells are clearly evident (*arrow*). **C**, The most common pathologic change seen in amiodarone toxicity is a cellular interstitial pneumonia associated with prominent intra-alveolar macrophages whose cytoplasm shows fine vacuolation. **D**, In some patients with amiodarone toxicity, an organizing pneumonia pattern develops, resulting in a mass effect on thoracic imaging studies. (From Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, pp 117–137, Figs. 5-32, 7-64, 7-66A.)

eFigure 71-24 Adalimumab-induced lung injury. **A–C**, Axial chest CT in a patient with rheumatoid arthritis undergoing adalimumab therapy shows multifocal bilateral ground-glass opacity with reticulation, consistent with an acute lung injury pattern. (Courtesy Michael Gotway, MD.)

Differentiating Work-Exacerbated Asthma
from Non-Work-Related Asthma or
Occupational Asthma
Socioeconomic Impact of Work-Exacerbated Asthma

INTRODUCTION

Work-related asthma (WRA) is a major public health concern due to its high prevalence and societal burden. WRA is a broad term indicating that asthma is worsened by the workplace.¹ WRA encompasses *occupational asthma* (OA), which is asthma caused by a specific agent at the workplace and *work-exacerbated asthma* (WEA), which corresponds to asthma exacerbated by nonspecific stimuli at the workplace but not caused by it (Fig. 72-1).²

Several definitions of OA have been proposed. The most recent has been published in the latest American College of Chest Physicians Consensus statement on WRA³: “Occupational asthma refers to de novo asthma or the recurrence of previously quiescent asthma (i.e., asthma as a child or in the distant past that has been in remission) induced by either sensitization to a specific substance (e.g., an inhaled protein [*high-molecular-weight* (HMW) protein of > 10 kD] or a chemical [*low-molecular-weight* (LMW) agent]), at work, which is termed sensititizer-induced OA, or by exposure to an inhaled irritant at work, which is termed irritant-induced OA.”

Sensitizer-induced OA has also been defined as “asthma with a latency period,” suggesting the presence of an underlying immunologic mechanism responsible for a latency period from the beginning of the occupational exposure to the onset of asthma symptoms.⁴

Irritant-induced (occupational) asthma (IIA), also called “OA without a latency period” or “nonimmunologic OA,”⁵ encompasses a wide spectrum of asthma phenotypes related to irritant mechanisms, as opposed to OA caused by immunologic mechanisms. The rapid onset of asthma within a few hours after a single exposure to high levels of irritant substances (i.e., acute-onset IIA or *reactive airways dysfunction syndrome* (RADS)⁶ is the best typified phenotype of IIA, whereas for other clinical phenotypes (e.g., “low-dose reactive airways dysfunction syndrome,” “not-so-sudden IIA,” or “IIA with latency”)^{7-13,13a} the causal relationship with workplace irritant exposures remains uncertain.

WEA has received growing attention during the past decade. The latest definition of WEA has been proposed by the American Thoracic Society Task Force on WEA² and consists of four criteria:

- There is preexisting or concurrent asthma. The onset of asthma may have predated current employment or happened first while at the worksite of interest but was not caused by specific exposures within that workplace.
- An increased frequency of asthma symptoms, medication use, or health care utilization is temporally associated with work. Medical test results may document more frequent abnormalities.
- Workplace exposures or conditions that can exacerbate asthma exist.
- Occupational asthma (asthma caused by a specific, identified workplace exposure) is unlikely.

In spite of these clear definitions, differentiating those conditions is often difficult in clinical practice. An accurate diagnosis is crucial because the diagnosis of this condition can result in a change of career and/or some financial compensation. This chapter reviews the epidemiology, pathophysiology, diagnosis, management, prevention, and socioeconomic impacts of sensitizer-induced OA, IIA, and WEA.

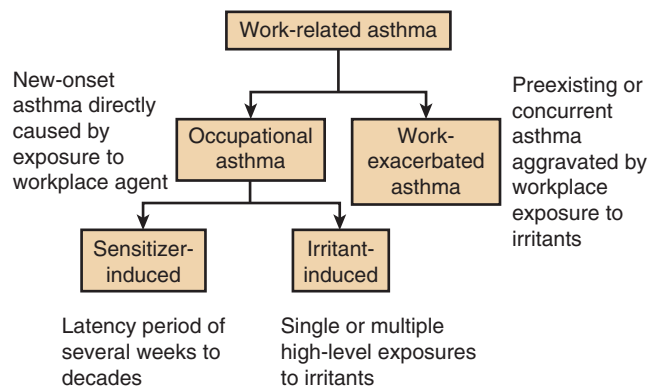

Figure 72-1 Categorization of work-related asthma into subsets based on the cause and timing of the asthma.

SENSITIZER-INDUCED OCCUPATIONAL ASTHMA

EPIDEMIOLOGIC ASPECTS

Estimates of the frequency of OA have been derived from various sources, including cross-sectional and longitudinal studies of high-risk workforces, occupational disease registries, voluntary notification programs, and population-based surveys. A pooled analysis of data published up until 2007 indicated that 17.6% of all adult-onset asthma is attributable to workplace exposures.¹⁴

Cross-sectional surveys of workforces exposed to sensitizing agents reported highly variable prevalence rates of OA, but these estimates are largely affected by the criteria used to identify the disease and selection biases. Prospective cohort studies reported incidence rates ranging from 1.8 to 4.1 cases of OA per 100 person-years among workers exposed to laboratory animals,¹⁵ wheat flour,¹⁶ and latex gloves.¹⁷ Incidence rates derived from notification schemes and compensation statistics in various countries ranged from 24 to 174 new cases per million active workers per year.¹⁸⁻²⁴ Differences from one country to another may result from geographic differences in industrial activities, as well as the heterogeneity in diagnostic criteria and data collection procedures.

The European Community Respiratory Health Survey II provided higher estimates of 250 to 478 incident cases of work-attributable asthma per million people per year.^{25,26} These data suggest that the disease remains largely unrecognized, although population surveys are affected by the lack of confirmation of OA through objective tests.

CAUSAL AGENTS

A large number of substances (>400) used at work can cause immunologically mediated OA.²⁷ They are usually categorized into HMW and LMW agents (Table 72-1). HMW

Table 72-1 Principal Agents Causing Occupational Asthma

Agent		Occupation/Industry
HIGH-MOLECULAR-WEIGHT AGENTS		
Cereals, flour	Wheat, rye, barley, buckwheat	Flour mills, bakers, pastry makers
Latex	Proteins from the Hevea tree	Health care workers, laboratory technicians
Animals	Mice, rats, cows, seafood	Laboratory workers, farmers, seafood processing
Enzymes	α-Amylase, maxatase, alcalase, papain, bromelain, pancreatin	Baking product production, bakers, detergent production, pharmaceutical industry, food industry
LOW-MOLECULAR-WEIGHT AGENTS		
Isocyanates	Toluene diisocyanate (TDI), methylene diphenyl-diisocyanate (MDI), hexamethylene diisocyanate (HDI)	Polyurethane production, plastic industry, insulation, molding, spray painting
Metals	Chromium, nickel, cobalt, platinum	Metal refinery, metal alloy production, electroplating, welding
Biocides	Formaldehyde, glutaraldehyde, quaternary ammonium compounds	Health care workers, cleaners
Persulfate salts	Hair bleach	Hairdressers
Acrylates	Cyanoacrylates, methacrylates, di- and tri-acrylates	Adhesives, dental and orthopedic materials, sculptured fingernails, printing inks, paints and coatings
Acid anhydrides	Phthalic, trimellitic, maleic, tetrachlorophthalic anhydrides	Epoxy resin workers
Reactive dyes	Reactive black 5, pyrazolone derivatives, vinyl sulphones, carmine,	Textile workers, food industry workers
Woods	Red cedar, iroko, obeche, oak, and others	Sawmill workers, carpenters, cabinet and furniture makers

agents are (glyco)proteins from plant and animal origins. LMW agents include chemicals, metals, and wood dusts. The intrinsic characteristics of occupational agents that determine their sensitizing potential remain largely uncertain. However, LMW agents causing OA are typically highly reactive electrophilic compounds that are capable of combining with hydroxyl, amino, and thiol functionalities on airway proteins. Quantitative structure-activity relationship models have identified a number of reactive groups that are associated with a high risk of respiratory sensitization (e.g., isocyanate [$\text{N} = \text{C} = \text{O}$], carbonyl [$\text{C} = \text{O}$], and amine [NH_2]), particularly when two or more groups are present within the same molecule.²⁸

Actually, a handful of agents (i.e., flour, diisocyanates, latex, persulfate salts, aldehydes, animals, wood dusts, metals, enzymes) usually account for the majority (50% to 90%) of reported cases of OA.^{24,29} Nevertheless, the distribution of causal agents may vary widely across geographic areas, depending on the pattern of industrial activities.¹⁸⁻²⁴ The highest incidence of OA is seen in bakers and pastry makers, other food processors, spray painters, hairdressers, wood workers, health care workers, cleaners, farmers, laboratory technicians, and welders.

PATHOPHYSIOLOGY

The pathophysiology of sensitizer-induced OA often involves an *immunoglobulin E* (IgE)-dependent mechanism. This mechanism is encountered mainly with HMW agents. Although specific IgE has also been encountered in OA due to LMW agents (e.g., platinum salts, trimellitic anhydride, other acid anhydrides), the production of specific IgE antibodies or the upregulation of IgE receptors has not been identified in the majority of cases of OA induced by LMW agents.³⁰

Immunologic, IgE-mediated

The pathophysiology of OA induced by IgE-dependent agents is similar to allergic asthma unrelated to work. HMW agents act as complete antigens and induce the production of specific IgE antibodies, whereas the LMW occupational agents that are likely to induce specific IgE antibodies do so by acting as haptens and binding with proteins to form functional antigens. The role of specific IgE is still controversial in isocyanate-induced asthma.³¹ The presence of specific IgE to isocyanates seems a good predictor of isocyanate-induced OA (specificity 89% to 100%),³ whereas specific IgG seems to be mostly associated with exposure to isocyanates.³² However, whether isocyanate-induced asthma is an IgE-mediated disease is still a matter of debate.³¹

Immunologic, non-IgE mediated

Cell-mediated reactions are likely to play an important role in OA due to LMW agents. Although the predominant immune response to chemical respiratory allergens may be of the *type 2 T helper* (Th2) type, other cells may play important support or regulatory roles. CD4- and CD8-positive T cells and different cytokines such as *interleukin* (IL)-1, IL-4, IL-5, IL-6, and IL-15 have been found in biopsies,³³ *bronchoalveolar lavage* (BAL), and the sputum of patients with isocyanate-induced asthma.³² Neutrophils are also likely to

be involved in isocyanate-induced asthma as shown by an increase in myeloperoxidase and IL-8 after exposure to *toluene diisocyanate* (TDI).³⁴ A mixed Th1/Th2 cytokine production has been observed in subjects with red-cedar-induced asthma.³⁵ Furthermore, a *specific-inhalation challenge* (SIC) test induced a mixed Th2/Th1 response in which CD8⁺ cells were the main producers of *interferon* (IFN)-gamma.³⁶

There is evidence that isocyanates can stimulate human innate immune responses by up-regulating immune pattern-recognition receptors of monocytes and increasing the chemokines that regulate monocyte/macrophage trafficking (*macrophage migration inhibitory factor* [MIF], *monocyte chemoattractant protein-1* [MCP-1]).³⁷ Furthermore, repetitive antigenic stimulation of diisocyanate asthmatic peripheral blood mononuclear cells induced the synthesis of *tumor necrosis factor* (TNF)- α , and MCP-1,³⁸ but not IL-4 or IL-5.³⁰

RISK FACTORS

OA results from the complex interaction between environmental and individual susceptibility factors (Table 72-2).²⁹

Environmental Factors

The intensity of exposure to sensitizing agents is currently the best identified and the most important environmental risk factor for the development of OA. There is strong evidence supporting a dose-response relationship between the level of exposure to HMW agents and the development of IgE-mediated sensitization and OA. Such a dose-response relationship has also been documented for some LMW agents, such as platinum salts, acid anhydrides, and isocyanates. Noteworthy, exposure-response relationships may be affected by individual susceptibility factors and the timing of exposure. For instance, the role of genetic susceptibility markers, such as certain HLA class II alleles, may become more apparent at low levels of exposure to occupational agents.³⁹ The incidence of WRA symptoms is consistently higher within the first 1 to 4 years of exposure to HMW agents, and exposure-response gradients are more clearly documented in this early period of exposure.¹⁵

A number of studies indicate that cigarette smoking can increase the risk of IgE-mediated sensitization to some HMW and LMW agents, but the evidence supporting an association between smoking and the development of clinical OA is still weak. The role of other environmental cofactors, such as nonrespiratory routes of exposure and concomitant exposure to endotoxin and pollutants at work, remains largely uncertain.

Host-Related Factors

Atopy has been consistently demonstrated as an important host risk factor for the development of IgE sensitization and OA, but only for HMW agents. Preexposure sensitization to common allergens that are structurally related to workplace allergens, such as exposure to pets in laboratory animal workers, could be a stronger risk factor for OA than atopy.

Prospective cohort studies suggested that the presence of nonspecific bronchial hyperresponsiveness^{40,41} and rhinitis^{41,42} before entering exposure to HMW occupational agents is an independent risk factor for subsequent IgE

Table 72-2 Potential Risk Factors for the Development of Occupational Asthma

Risk Factor	Evidence	Agents/Settings
ENVIRONMENTAL FACTORS		
High level of exposure	Strong Moderate	HMW agents LMW agents: platinum salts, acid anhydrides, isocyanates
Cigarette smoking	Moderate Weak	(For IgE sensitization) Laboratory animals, snow crab, prawn, salmon, psyllium, green coffee, enzymes, acid anhydrides, platinum, reactive dyes (For clinical OA) Laboratory animals, enzymes
Skin exposure	Weak	Isocyanates
HOST-RELATED FACTORS		
Atopy	Strong Weak	HMW agents LMW agents: platinum, acid anhydrides
Genetic markers		
HLA class II alleles	Moderate	LMW agents: isocyanates, red cedar, acid anhydrides, platinum salts HMW agents: laboratory animals, latex
Antioxidant enzymes*	Moderate	Isocyanates
SNPs of α -T catenin	Moderate	Isocyanates
TLR4 polymorphisms	Weak	Laboratory animals
IL-4 receptor alpha and IL13 polymorphisms	Weak	Isocyanates
Preexisting nonspecific bronchial hyperresponsiveness	Moderate	HMW agents (laboratory animals, flour, latex)
Work-related rhinitis	Strong	Laboratory animals
Gender (female)	Weak	Snow crab processors

*Glutathione-S-transferase and N-acetyltransferase.

HMW, high-molecular-weight; IL, interleukin; LMW, low-molecular-weight; OA, occupational asthma; SNPs, single nucleotide polymorphisms; TLR4, Toll-like receptor-4.

sensitization to these allergens. On the other hand, there is strong evidence that the development of occupational rhinitis during exposure is associated with an increased risk for the development of OA.^{43,44} However, the proportion of subjects with occupational rhinitis who will develop OA remains unknown. Among workers exposed to laboratory animals, the predictive value of work-related nasal symptoms on the subsequent development of probable OA was only 11.4% over a follow-up period of 30 to 42 months.

Certain HLA class II molecules (i.e., HLA-DR, HLA-DQ, and HLA-DP alleles), which are involved in the presentation of processed antigens to T lymphocytes, were found to confer either susceptibility or protection against OA due to various LMW and HMW occupational allergens.⁴⁵ There is also some suggestion that genes associated with Th2-cell differentiation (i.e., polymorphism of the IL-4 receptor alpha-chain, *IL13*, and *CD14* [C159T] genes) could play a role in the development of OA. Genes involved in the protection against oxidative stress, such as *glutathione-S-transferase* (GST) and *N-acetyltransferase* (NAT), have been associated with an increased risk of isocyanate-induced OA (i.e., *GSTM1* null genotype and slow N-acetylator phenotypes) or a protective effect (i.e., *GSTP1**Val/Val allele). Overall, the currently available information indicates that genetic markers have a low predictive value in identifying susceptible workers. In addition, there is convincing evidence that a wide variety of environmental factors can interact with genetic determinants to affect disease susceptibility.

DIAGNOSIS

The diagnosis of OA is difficult to establish. A comprehensive and integrated approach including the assessment of occupational history, clinical symptoms, and functional

and inflammatory characteristics at baseline and in response to exposure to occupational agents needs to be undertaken in order to achieve an accurate diagnosis. This approach is summarized in [Figure 72-2](#). Each step of the investigation has substantial limitations that may be attenuated by the combination of several tests.⁴⁶ The validity of the different diagnostic tests and their practical limitations and advantages are summarized in [Table 72-3](#).

OA should be suspected in every adult with new-onset asthma. Although the respiratory symptoms (e.g. wheezing, dyspnea, chest tightness, cough, and sputum production) are similar to those encountered in *non-WRA* (NWRA), in OA, their appearance and severity is usually modulated by the work exposure. The symptoms can start at the beginning of the work shift or toward its end or even after working hours with remission or improvement during weekends and holidays. Rhinitis is associated with respiratory symptoms in the majority of cases of OA and often precedes the respiratory symptoms, especially with exposure to HMW agents. Although a thorough clinical and occupational history must be carefully recorded, the diagnosis of OA cannot be made only on the basis of a compatible history, which has a low positive predictive value.⁴⁷

A good occupational history must detail not only the current employment and exposure but also the past employments and exposures. The work history (current and past employments), the symptoms (nature and temporal relationship to work), as well as the potential risk factors, need to be recorded.⁴⁸ The substances to which the worker is potentially exposed at work can be checked against a comprehensive list of agents recognized as causing OA, and the person's employment can be searched on the list of at-risk occupations.³ *Material safety data* (MSD) sheets can be requested from the workplace and may be of help in clarifying the presence of a workplace sensitizer. If the content of

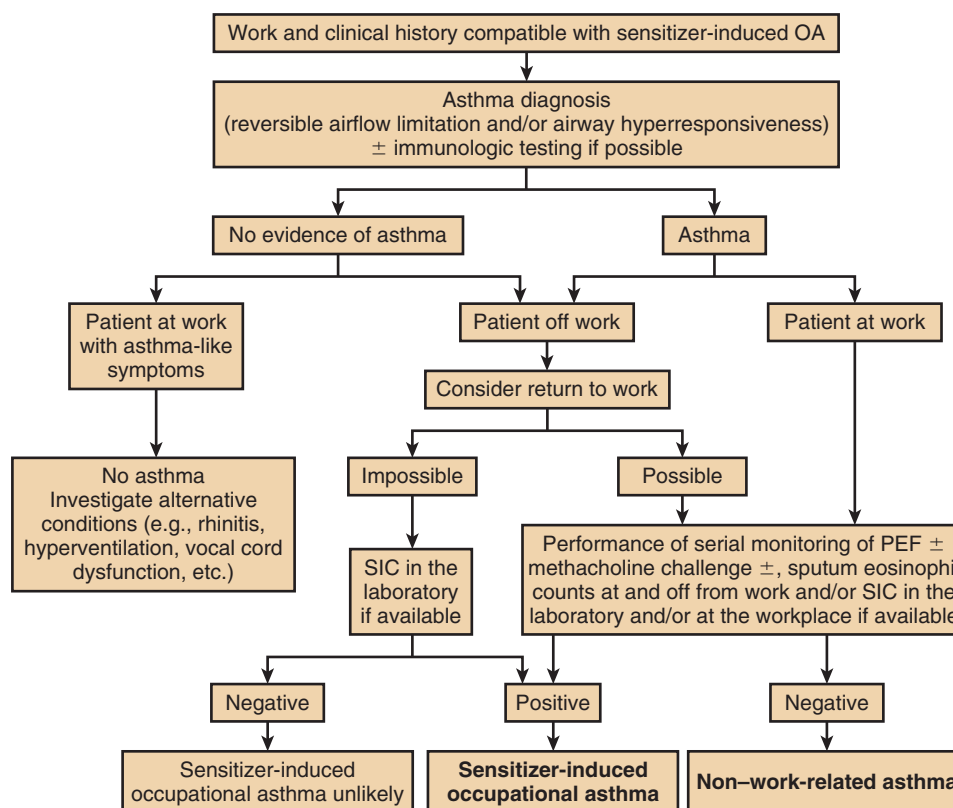

Figure 72-2 Diagnostic approach in the investigation of sensitizer-induced occupational asthma. OA, occupational asthma; PEF, peak expiratory flow rates; SIC, specific inhalation challenge.

the causal agent is less than 1%, it may not be listed in the MSD. If available, the occupational health record and the industrial hygiene record from the company should also be reviewed. A list of *agents* responsible for OA can be found at: http://www.asthme.csst.qc.ca/document/Info_Gen/AgenProf/Bernstein/BernsteinAng.htm.

A list of *occupations* in which the exposure to those agents is encountered can be found at: [http://www.asthme.csst.qc.ca/document/Info_Med/IdCauses/Bernstein/Occupational Asthma-Agents by occupation.pdf](http://www.asthme.csst.qc.ca/document/Info_Med/IdCauses/Bernstein/Occupational%20Asthma-Agents%20by%20occupation.pdf).

Once the history has been obtained, the diagnosis of asthma should be confirmed by documenting reversible airflow limitation and/or airway hyperresponsiveness. However, the lack of airway hyperresponsiveness does not exclude the diagnosis of OA in subjects who have been removed from exposure. Immunologic testing is useful in demonstrating a sensitization of the worker to the suspected agent. Although the negative predictive value of these tests is high in the case of HMW, they are limited by the lack of standardized commercially available reagents for skin and in vitro tests. Skin-prick tests are seldom useful when LMW agents are suspected.

The work-relatedness of asthma should be assessed through serial measurements of *peak expiratory flow* (PEF) and/or nonspecific bronchial hyperresponsiveness at work and off work and/or specific inhalation challenges in the laboratory or at the workplace.

Assessing airway responsiveness is an important step in the investigation of OA. It may confirm not only the diagnosis of asthma but also the improvement of airway responsiveness after a period away from work, which may support

the diagnosis of OA. However, additional studies assessing the predictive positive and negative values of serial measures of nonspecific bronchial hyperresponsiveness at and away from work for diagnosing OA are required to know the diagnostic performance of this test. Nonetheless, normal airway responsiveness after a period at work at which time the workers experience their respiratory symptoms makes the diagnoses of OA and asthma improbable. In this case, an alternative diagnosis should be investigated.³

As said, a serial measurement of PEF at work and away from work has been found to be useful in confirming OA.⁴⁸ The minimum period of PEF monitoring should be 2 weeks at work with a significant exposure to the suspected causative agent and a similar period away from work, unless significant changes are recorded earlier at work. Asthma treatment should be kept constant throughout the period of monitoring. However, similarly to common asthma, compliance with PEF monitoring has been shown to be poor and the results may be falsified if an electronic PEF meter is not used.⁴⁹

SIC tests consist of exposing the subjects to the suspected occupational agent in the laboratory and/or at the workplace.^{50,50a} These tests are considered to be the reference tests, but they are time consuming and require specialized facilities available in only a few centers. Specific-challenge tests are useful when (1) the diagnosis of OA remains in doubt after serial monitoring of PEF or airway responsiveness; (2) a patient clearly has OA, but the causal agent needs to be identified; (3) a new agent is suspected of causing OA; and (4) the patient cannot be returned to the incriminated workplace. A false-negative response may be obtained if the wrong agent is used or if the exposure

Table 72-3 Advantages and Limitations of the Diagnostic Tests Used in the Investigation of Occupational Asthma

Diagnostic Tests	Advantages and Limitations
Assessment of nonspecific bronchial hyperresponsiveness	<ul style="list-style-type: none"> ■ Simple, low cost. ■ Confirms the diagnosis of asthma. ■ Low specificity for diagnosis of OA. The absence of airway hyperresponsiveness does not exclude the diagnosis of OA in subjects who have been removed from the workplace.
Immunologic tests	<ul style="list-style-type: none"> ■ Easy to perform, low cost. ■ Commercial extracts are available (skin prick tests or specific IgE for HMW agents). ■ Measurement of specific IgE available for some LMW agents (anhydrides, acids, isocyanates, aldehydes), but low sensitivity. ■ Lack of standardization for the majority of occupational allergens except for latex. ■ Can identify the sensitization but not necessarily the disease.
PEF monitoring	<ul style="list-style-type: none"> ■ Low cost. ■ Requires the workers' collaboration. ■ Low adherence (<60%). ■ Possible falsification of results. ■ Requires 2 weeks at and away from work, which is not always possible. ■ Impossible to perform when the worker has been removed from work. ■ No standardized method for interpreting the results. ■ Interpretation of the results requires experience.
Specific-inhalation challenges in the laboratory	<ul style="list-style-type: none"> ■ Confirmation of the diagnosis of OA when the test is positive. ■ False-negative tests are possible. ■ Costly. ■ Available in a small number of centers worldwide.
Specific-inhalation challenges at the workplace	<ul style="list-style-type: none"> ■ Exclude diagnosis if negative when performed in the usual work conditions. ■ Requires usual work conditions. ■ Costly.
Noninvasive measures of airway inflammation	<p>Sputum cell counts</p> <ul style="list-style-type: none"> ■ Impossible to falsify ■ Bring additional evidence to the diagnosis of OA ■ Costly ■ Not widely available ■ Does not confirm or exclude the diagnosis of OA by itself <p>Exhaled NO</p> <ul style="list-style-type: none"> ■ Easy to perform ■ Inconsistent results ■ Difficult to interpret ■ Affected by many different factors

conditions are not comparable with those in the workplace. SICs have been shown to be safe and induce rarely severe asthmatic reactions requiring administration of systemic steroids.^{50b}

Noninvasive measures of airway inflammation are increasingly used during the investigation of OA. There is evidence that OA is associated with an increase in the sputum eosinophil percentage during periods at work and a decrease after removal from exposure.^{51,52} In settings where this tool is available, it may complement the current investigation of OA. Although the measurement of *fractional exhaled nitric oxide* (FeNO) is easier to obtain than sputum cell counts, the current evidence does not show a clear benefit of using FeNO in the investigation of OA.⁵³ The interpretation of an increased FeNO is more difficult than sputum differential cell counts due to its lack of specificity, as well as the potential confounding factors that may influence the results. However, recent evidence shows a high specificity of this test in subjects exposed to HMW agents.⁵⁴ Whether the monitoring of FeNO should be used in some phenotypes of OA remains to be determined.⁵⁴ Making an accurate diagnosis of OA is crucial due to the significant social and financial consequences associated with this diagnosis.

OUTCOME AND MANAGEMENT OF SENSITIZER-INDUCED ASTHMA

According to recent systematic reviews of the existing data, the complete avoidance of exposure to the causal agent remains the optimal treatment of immunologic OA.^{55,56} Although a reduction of exposure to the agent can be considered as an alternative option, the limited available evidence indicates that this option is less beneficial than complete cessation of exposure because it is associated with a lower likelihood of asthma improvement and a higher risk of worsening.⁵⁷

Immunotherapy has only been tested in workers with allergy and/or OA to HMW agents for which an IgE-dependent reaction has been demonstrated. Immunotherapy has been mainly tested in health care workers allergic to latex.⁵⁸ Although immunotherapy can reduce cutaneous and respiratory symptoms in health care workers allergic to latex, this treatment can induce systemic reactions in a large number of treated subjects.⁵⁹ Small or uncontrolled studies have reported an improvement of allergic and respiratory symptoms after immunotherapy to some selected agents (cereal,⁶⁰ sea squirt,⁶¹ laboratory animal,⁶² and wood⁶³). However, whether immunotherapy can alter the

course of OA in the long term remains to be determined. Further studies need to be conducted before immunotherapy can be recommended for the treatment of OA to HMW agents.

A few case reports provided some suggestion that treatment with the anti-IgE omalizumab could improve asthma control in subjects with flour-induced OA, who remain exposed to the causal work environment, although further prospective investigations are required in subjects who choose to continue exposure.³

Clinicians should be aware that OA is not always reversible after cessation of exposure to the sensitizing agent. Asthma symptoms and *airway hyperresponsiveness* (AHR) persist in approximately 70% of the patients with OA several years after removal from the offending environment.⁶⁴ Besides environmental interventions, the pharmacologic treatment of OA should follow the clinical practice guidelines for asthma.⁶⁵

Primary prevention aims at preventing the development of immunologic sensitization to workplace agents and subsequent OA.^{3,66} Primary preventive strategies should focus on the control of workplace exposures because there is strong evidence supporting a dose-response relationship between the level of exposure to sensitizing agents and the development of OA. The control of exposure can be achieved through a panel of measures that include the elimination of agents with a known sensitizing potential whenever feasible: (1) the modification of sensitizing materials (e.g., encapsulation of detergent enzymes); (2) the substitution of highly sensitizing agents by materials with lower asthmagenic potential (e.g., nonvolatile oligomers of diisocyanates, latex gloves with a lower content in powder and protein allergens); (3) engineering changes to the workplace (e.g., exhaust ventilation, enclosure of industrial processes); (4) information and education of workers and employers on safe work practices; and (5) the use of personal protective equipment for specific tasks.^{67,68} Another approach is to identify susceptible individuals at the time of preemployment examination and exclude them from employment or from high-risk jobs. This strategy is inefficient and unduly discriminating because the currently identified markers of individual susceptibility (see Table 72-2) offer only a low positive predictive value for the development of OA, especially when these markers, such as atopy, are highly prevalent in the general population.³ Nevertheless, physicians caring for adolescents with asthma and allergic diseases may offer useful advice regarding careers in which their underlying atopic status increases the risks for work-related sensitization to HMW agents.⁶⁹

Secondary prevention of sensitizer-induced OA involves the detection of the disease process at an early (preferably preclinical) stage to modify the disease process through appropriate interventions to eliminate exposure. The rationale underlying secondary prevention is the consistent finding that the outcome of OA is better with an early diagnosis and milder disease at the time of removal from exposure.^{64,70} Increasing awareness of the disease among workers and health professionals is a key step to enhance the recognition of OA because the condition still remains underdiagnosed and inappropriately investigated.⁷¹ There is recent evidence that appropriately designed surveillance

programs are effective in identifying OA in subjects with less severe asthma and a more favorable outcome.⁷²

A few observational studies and historical data indicate that prevention is effective in reducing the incidence of OA and occupational rhinitis caused by natural rubber latex in health care workers,⁷³ enzymes in the detergent industry,⁷⁴ flour,⁷⁵ laboratory animals,⁷⁶ and isocyanates.⁷² However, available data do not distinguish the relative effect of the diverse components of prevention strategies because they are usually implemented as multicomponent programs targeting education, control of exposure, and medical surveillance.

SOCIOECONOMIC IMPACT

Studies worldwide have shown that OA is associated with substantial financial consequences for affected workers and society as a whole.^{77,78} There is growing evidence that WRA is associated with more severe asthma^{79,80} and with a higher health care resource utilization⁸¹ as compared with asthma unrelated to work. In addition, OA generates higher indirect costs than nonoccupational asthma because the former condition most often requires job changes to either avoid or reduce exposure to the causative agent.⁸² Follow-up studies of workers with OA have consistently documented that the condition is associated with a high rate of prolonged unemployment, ranging from 18% to 69%, and a reduction in work-derived income in 44% to 74% of affected workers.⁸³ A poorer socioeconomic outcome is associated with the need for a complete avoidance of exposure to the sensitizing agent, a lower level of education, an older age, and lack of effective job retraining programs.⁸³

Because the specific bronchial hyperreactivity to occupational agents almost never completely disappears, workers with OA should be considered as permanently and completely disabled for jobs involving exposure to the sensitizing agent that caused their OA.⁸⁴ They should be thoroughly informed about the possibilities for compensation, and established cases should be reported to the appropriate public health authorities, according to national regulations. Evaluation of physiologic impairment should take into account the characteristic features of asthma and should be based on the level of airway obstruction, the degree of nonspecific bronchial hyperresponsiveness, and the intensity of medication required for controlling asthma.³

IRRITANT-INDUCED ASTHMA

EPIDEMIOLOGIC ASPECTS

Surveillance programs conducted in various countries indicated that RADS and IIA account for 5% to 18% of all reported cases of WRA.⁸⁵ However, few population-based surveys have addressed the impact of acute inhalation incidents on the global burden of asthma. The longitudinal part of the European Community Respiratory Health Survey found that reported acute inhalation incidents were associated with a higher risk of new-onset asthma.²⁶ Several cross-sectional studies revealed that asthmatic individuals more often report a history of a single high-level exposure to irritant cleaning products than healthy controls.⁸⁶⁻⁸⁸ A

longitudinal study of rescue and recovery workers exposed to high levels of alkaline dust during and after the World Trade Center disaster showed an increased risk of new-onset asthma in the follow-up period of 5 to 6 years, particularly in the first months after exposure.⁸⁹

Longitudinal workforce-based studies have documented an increased risk of asthma among workers with repeated exposures to high levels of chlorine, ozone, and sulphur dioxide in metal production and pulp mill workers.⁹⁰⁻⁹² Exposures to high levels of irritants in the workplace are called “gassings” and are often recalled by workers in epidemiologic studies. Few epidemiologic studies have supported the role of repeated and/or chronic exposure to lower levels of irritant compounds at work in the development of asthma, with the exception of workers exposed to cleaning agents.⁹³ In these populations, the frequent use of chlorine bleach and ammonia has been associated with an increased risk of asthma.^{86,94} A spectrum of exposures to irritant agents are likely to induce different clinical presentations of asthma ranging from RADS, when subjects are exposed to high concentrations of irritants agents, to “low-dose reactive airways dysfunction syndrome,” “not-so-sudden IIA,” or “IIA with latency” when subjects are exposed to irritants at lower concentrations. However, “low-level” irritant-induced asthma cannot currently be reliably diagnosed in the individual worker.

PATHOPHYSIOLOGY

Several factors may influence the pulmonary responses to irritants, such as the intensity of exposure, physical properties (e.g., vapor pressure, solubility), and the chemical reactivity.⁹⁵ Although many irritants are odorous and pungent, it is worth remarking that odor is not related to toxicity. The resulting biologic effect will depend on the depositing of the irritant in the upper and/or lower airways. Water-soluble irritants and particles with an aerodynamic diameter larger than 5 μm are predominantly deposited in the upper respiratory tract and proximal airways. Water-insoluble agents and particles of 0.5 to 5 μm can reach the distal airways and alveoli, often without causing much sensory irritation (see Chapters 11 and 75).

The development of acute IIA has been associated with a wide variety of high-level exposures to irritant fumes, gases, sprays, or even dusts (Table 72-4).⁹⁶ Typically, the exposure is caused by spills of volatile compounds, accidental releases of irritants under pressure, accidental fire with release of complex mixtures of thermal degradation products, or inadvertent reduction of the air ventilation rate in a confined space.⁹⁵ The nature and concentrations of inhaled irritants generated during workplace exposure incidents are most often unavailable.

Inhaled irritants provoke epithelial cell damage and persistent inflammatory response and airway remodeling, although the precise pathophysiologic mechanisms leading to persistent asthma remain largely speculative.⁹⁵ Bronchial biopsy samples obtained after a high-level exposure to irritants revealed marked epithelial desquamation, inflammatory changes with predominance of lymphocytes, airway remodeling, and collagen deposition in the bronchial wall.^{97,98} Similar changes have been described in animal models.⁹⁹⁻¹⁰¹ Two studies provided information on the long-

Table 72-4 Examples of Exposures Causing Acute Irritant-Induced Asthma

Exposure	Examples
Gases	Chlorine (e.g., released by mixing sodium hypochlorite with acids), chloramines (released by mixing sodium hypochlorite with ammonia), sulfur dioxide, nitrogen oxides, dimethyl sulfate
Acids	Acetic, hydrochloric, hydrofluoric, hydrobromic acids
Alkali	Ammonia, calcium oxide (lime), hydrazine
Biocides	Formalin, ethylene oxide, fumigating agents, insecticides (sodium methyldithiocarbamate, dichlorvos)
Halogenated derivatives	Bromochlorodifluoromethane (fire extinguisher), trifluoromethane, chlorofluorocarbons (CFC, thermal degradation products of freons), uranium hexafluoride, hydrogen and carbonyl fluoride
Solvents	Perchloroethylene
Fumes	Diesel exhaust, paint fumes, urea fumes, fire smoke, iodine compounds (iodine and aluminium iodide, hydrogen iodide), diethylaminoethanol (corrosion inhibitor)
Sprays	Paints (not specified), floor sealant (aromatic hydrocarbons)
Dusts	World Trade Center alkaline dust, calcium oxide (lime)
Potential sensitizers	Isocyanates, phthalic anhydride

term outcome of airway inflammation and remodeling in a large series of subjects with acute IIA.^{98,102} Both showed an inflammatory profile similar to what has been described in sensitizer-induced OA after removal from exposure, with an increase of eosinophils in some patients or neutrophils in others. However, in patients with IIA, subepithelial fibrosis was more prominent than in those with sensitizer-induced asthma. Altogether, in IIA, the pathologic changes observed during the acute phase are consistent with an acute toxic injury, whereas the long-term phase is similar to sensitizer-induced OA.

RISK FACTORS

The environmental and host factors that determine the initiation and persistence of IIA remain largely unknown. A relationship between the level of exposure assessed qualitatively by industrial hygienists and the prevalence of nonspecific bronchial hyperresponsiveness has been documented in subjects who had been exposed to a spill of acetic acid.¹⁰³ In a follow-up survey of pulp mill workers exposed to high levels of chlorine, the severity of gassing incidents, as evidenced by hospital emergency department visits, was a more significant risk factor for the persistence of nonspecific bronchial hyperresponsiveness than was the number of incidents.¹⁰⁴ The development of IIA did not appear to be associated with smoking and atopy.^{103,104} Among the World Trade Center rescue and cleaning workers, the main risk factors for the development of a respiratory disease were the presence on the site during the first 48 hours and the duration of exposure during rescue and cleaning.¹⁰⁵ Smoking was a predisposing or an additive risk factor, whereas atopy was identified as a risk factor for upper, but not for lower, airway disease.

Table 72-5 Diagnostic Criteria for the Reactive Airways Dysfunction Syndrome (i.e., Acute Onset Irritant-induced Asthma)

1. Absence of preexisting asthma symptomatology or a history of asthma in remission
2. Onset of asthma symptoms after a single specific inhalational exposure or accident
3. Exposure to an irritant vapor, gas, fume, or smoke in high concentration
4. Onset of asthma symptoms within minutes to hours and less than 24 hours after the exposure
5. Presence of airflow limitation with a significant bronchodilator response or nonspecific bronchial hyperresponsiveness to histamine/methacholine
6. Exclusion of other pulmonary disorders that can explain the symptoms or simulate asthma

Adapted from Brooks SM, Weiss MA, Bernstein IL: Reactive airways dysfunction syndrome (RADS). Persistent asthma syndrome after high level irritant exposures. *Chest* 88(3):376–384, 1985; Brooks SM, Bernstein IL: Irritant-induced airway disorders. *Immunol Allergy Clin North Am*. Nov31(4):747–768, 2011; Tarlo SM, Balmes J, Balkissoon R, et al: Diagnosis and management of work-related asthma: American College of Chest Physicians Consensus Statement. *Chest* 134(3 Suppl):15–41S, 2008.

DIAGNOSIS

RADS (i.e., acute IIA) is characterized by the onset of asthma symptoms within 24 hours after a single, most often accidental, high-level exposure to a wide variety of irritant substances in subjects without preexisting asthma. Brooks and coworkers proposed stringent clinical and functional criteria for the diagnosis of this condition (Table 72-5).^{3,6} The presence of asthma should be substantiated by spirometry demonstrating airflow limitation with a significant bronchodilator response or nonspecific bronchial hyperresponsiveness to methacholine or histamine. Conditions with similar clinical manifestations, such as irritant-induced vocal cord dysfunction, should be carefully considered.³ The causal role of the workplace exposure can be documented with a reasonable level of confidence by the strong temporal association between an inhalation accident and the rapid onset of asthma symptoms. Such cases should be considered as “definite” IIA. Nevertheless, the World Trade Center tragedy brought new insights by suggesting that asthma can develop insidiously over a few months after a massive exposure to a complex mixture of alkaline dust and combustion products.^{106,107} In subjects who reported multiple high-level exposures to irritants, though less clearly massive than in RADS, the causal relationship can be supported by the documentation of repeated symptomatic inhalation accidents requiring medical care or reports to first aid units or occupational health services. These subjects should be regarded as having “probable” IIA.

There are some clinical features that clearly distinguish acute IIA from sensitizer-induced OA. Unlike sensitizer-induced OA, acute IIA does not require a latency period of exposure before the appearance of asthma, but an apparent latency period can be present in IIA that develops after multiple high-level exposures. Subjects with IIA do not develop WRA symptoms after reexposure to low concentrations of the irritant that initiated the symptoms because they are not “sensitized” to the offending agent. However, subjects with acute IIA may experience WRA symptoms because

their nonspecific bronchial hyperresponsiveness makes them more susceptible to irritant stimuli at work. The development of specific bronchial hypersensitivity has been documented after a single, intense exposure to some LMW chemicals.¹⁰⁸ Conversely, known sensitizers can induce IIA when inhaled at high concentrations.^{109,110} In such instances, specific inhalation challenges with the suspected agent may be useful in distinguishing IIA from sensitizer-induced-OA.

In the clinical reports that described the onset of asthma after repeated, often daily exposure to “moderate” levels of respiratory irritants at work, the evidence supporting the work-relatedness of asthma was weak and relied on the following findings: (1) a history of adult onset of asthma (or even the reactivation of a previously quiescent asthma⁹); (2) a history of repeated exposure to irritants; and (3) the absence of an identified sensitizer in the subject’s working environment. Distinguishing IIA attributed to repeated, moderate level exposures from coincidental asthma that is not work-related is elusive on a clinical basis. The possibility of “chronic/delayed-onset IIA” can only be inferred from epidemiologic studies documenting an increased risk of adult-onset asthma in certain occupations that are associated with frequent “moderate/excessive” exposures to irritant compounds.

OUTCOME AND TREATMENT

The few available data on the outcome of IIA indicate that it is quite similar to what has been described in subjects with sensitizer-induced OA after avoidance of exposure to the causal agent. Nonspecific bronchial hyperresponsiveness can improve over several years after an acute symptomatic inhalation accident.^{104,111} On the long term, however, about three quarters of subjects with acute IIA show persistent nonspecific bronchial hyperresponsiveness and require treatment with inhaled corticosteroids.¹¹²

Limited data exist on the management of IIA, and they are mainly related to case reports of acute IIA.¹¹³ There is some evidence that subjects with IIA benefit rapidly from treatment with oral and/or inhaled corticosteroids, although the dose and duration of treatment remains unknown. Unlike workers with sensitizer-induced OA, those with acute IIA may be able to continue in their usual jobs with appropriate asthma management, although they may subsequently experience worsening of their asthma symptoms on exposure to irritants at work, which may substantially reduce their capacity to work in polluted or dusty environments. The management of IIA may be further complicated by associated disorders, such as chronic rhinitis, perceived intolerance to multiple chemicals, and post-traumatic stress syndrome, which can result from an accidental exposure to irritant substances at work.^{89,112,114}

PREVENTION

Prevention of IIA should be primarily aimed at eliminating the risk of high-level exposures that can cause asthma. Such strategies should be directed toward the control of exposures to safe levels by occupational hygiene measures such as containment and adequate ventilation. Continuous monitoring of airborne concentrations of potential

respiratory irritants and alarm systems to detect peak exposures may be appropriate in some settings. An important component of prevention is the implementation of workers' educational programs on safe handling of chemicals, effective use of personal protective equipment, and measures to take in the event of an accident at work.

WORK-EXACERBATED ASTHMA

EPIDEMIOLOGIC ASPECTS

The prevalence of WEA reported in the literature varies according to the definition and the type of settings (clinical vs. epidemiologic) in which the WEA was assessed. Twelve studies have provided overall estimates of prevalence of WEA. These studies were conducted in the general population or in general health care settings in seven countries. The definition of asthma was not consistent and included physician-diagnosed asthma as determined from self-reports or medical records, or diagnosis based on an objective measurement of pulmonary function.^{115,116} Some of the studies reported prevalence as a percentage of all adults with asthma, and others as a percentage of all working adults with asthma. The prevalence of WEA from these 12 studies ranged from 13% to 58%, with a median of 21.5%. In the study where WEA was diagnosed according to changes in PEF between periods at and away from work, the prevalence of WEA was 14% in asthmatic workers.¹¹⁷ The most recent systematic review of the literature estimates that 21.5% of the cases of asthma are exacerbated by conditions at the workplace.² Therefore, although the prevalence varies quite widely from one study to another due to the definition and the population of interest, the prevalence of WEA can be estimated to be around 20% of the adult asthma population, which constitutes a substantial proportion of the whole asthmatic population.

PATHOPHYSIOLOGY

The pathophysiology of WEA is likely to be largely dependent on the type of triggers inducing asthma exacerbations. There is no reason to believe that the pathophysiology of WEA is different from the pathophysiology of asthma exacerbations observed in NWRA when the triggers are common allergens. When triggers consist of irritant agents, it is likely that the pathophysiology resembles what is seen in IIA. An airway epithelium injury is likely to play a pivotal role, and the injury intensity of the epithelial layer may be correlated with the respiratory function impairment as demonstrated in New York firefighters who intervened on 9/11.¹¹⁸ In murine models of chlorine exposure, oxidative stress plays a pivotal role in the pathogenesis of this condition and the administration of antioxidants can mitigate the epithelial damage.¹¹⁹ As shown in the animal models of chlorine exposure, the extent of the damage is likely to depend on the dose of the irritant agent inhaled.

WORK EXPOSURES ASSOCIATED WITH WORK-EXACERBATED ASTHMA

The identification of exposures associated with WEA has been reported either in studies that recorded the agents to

which the subjects with WEA were exposed in clinical settings, surveillance programs, or worker compensation programs or by using a risk-set approach, testing associations between occupational exposures and WEA while controlling for potential confounders. The studies assessing individual cases of WEA were performed mainly in North America¹²⁰⁻¹²⁸ or Europe.¹²⁹ The most commonly described agents were chemicals, dust, smoke, paints, and cleaning products. Although less frequently encountered than these agents, physical factors such as exercise,¹²⁸ temperature,¹²⁰ or emotional stress¹²¹ have also been reported to be associated with WEA.

DIAGNOSIS OF WORK-EXACERBATED ASTHMA

WEA should be suspected in all patients whose asthma is difficult to control, in patients who complain of a worsening of their symptoms, or in those who require an increase of their asthma medication when at work.³

Before establishing a diagnosis of WEA, the diagnosis of asthma needs to be confirmed by objective measures. Most asthma guidelines recommend the performance of spirometry, both prebronchodilator and postbronchodilator in order to show a FEV₁ reversibility of 12% with an absolute increase of at least 200 mL.¹³⁰ In the absence of a reversible airflow limitation, the measurement of airway hyper-responsiveness can confirm the diagnosis of asthma. The lack of objective confirmation of the diagnosis of asthma can lead to misdiagnosis in 30% of cases.¹³¹ Furthermore, nonspecific respiratory symptoms are frequent and can mimic asthma in workers exposed to a dusty or irritant environment.¹³²

The diagnosis of WEA relies on the demonstration of (1) a relationship between asthma exacerbations and occupational exposures or (2) poor asthma control during periods at work, along with (3) the determination that OA is unlikely. Asthma exacerbations or loss of asthma control can be documented by a change in the frequency and severity of asthma symptoms or by the need for an increase in asthma medications. Asthma exacerbations can also be documented by the need for emergency visits or hospitalizations or by changes in respiratory function at work. Serial PEF monitoring can show increased variability during periods at work compared with periods away from work.¹³³ Identifying the factors that trigger asthma symptoms is important to not only confirm the diagnosis of WEA but also decrease or remove the adverse environmental conditions at the workplace. Identifying multiple triggers is common because the workers are frequently exposed to several agents concomitantly.

Although there are limited data concerning the management of WEA, professional organizations have advised minimizing exposures at work and optimizing standard medical management for asthma (e.g., pharmacologic treatment, avoidance of symptom triggers).^{3,134} Although there is clear evidence that a persistent exposure to the occupational agent that caused their asthma is detrimental for workers with OA,⁵⁵ the impact of continuing exposure to triggers for WEA has not been well studied and thus is unknown at this time. There is limited evidence that workers with OA may have a greater improvement in their lung function and asthma control than subjects with WEA when removed from exposure.¹³⁵⁻¹³⁷

DIFFERENTIATING WORK-EXACERBATED ASTHMA FROM NON-WORK-RELATED ASTHMA OR OCCUPATIONAL ASTHMA

A few studies have compared workers with WEA to adults with NWRA. The clinical characteristics of workers with WEA did not differ greatly from adults with NWRA. Some studies reported that workers with WEA tended to be older,^{135,138} while others found an increased proportion of smokers in subjects with WEA.⁸¹ No specific risk factors have been clearly identified for WEA.

Workers with WEA are often difficult to differentiate from asthmatic subjects with OA, especially in cases who report a new onset of asthma while in the current workplace. The studies that compared subjects with WEA and OA report discrepant findings that can be explained by the different populations studied (general population vs. tertiary clinics). On the basis of U.S. cases that fulfilled the surveillance case definitions set by the *Sentinel Event Notification System for Occupational Risks* (SENSOR), Goe and colleagues¹³⁹ found that subjects with WEA were more likely to be female, young, nonwhite, and nonsmokers. These findings were not confirmed in the studies where WEA cases were from a referral clinic and defined by a worsening of asthma symptoms when at work and a negative SIC to the suspected agent(s).^{52,140}

Lemière and colleagues¹³⁷ found that after adjusting for age, asthma control, and FEV₁, the diagnosis of WEA was associated with more frequent prescriptions of inhaled corticosteroids, a noneosinophilic phenotype, and a trend toward a higher proportion of smokers than the diagnosis of OA.

The timing of the onset of asthma with respect to the start of employment at the workplace does not necessarily differentiate WEA from OA; for example, Larbanois and colleagues¹⁴⁰ defined WEA by the presence of WRA symptoms and a negative SIC and showed that only 7% of the 71 WEA subjects had asthma before employment. Also, onset of asthma before employment in the workplace of interest does not preclude the diagnosis of OA. Workers with previously diagnosed asthma can become sensitized to a new

agent at their workplace and develop OA. An increase in asthma symptoms or severity is usually noticed at this time.

In both WEA and OA, there is a worsening of asthma symptoms when at work with an improvement when removed from exposure. Serial PEF monitoring can show a greater variability during periods at work compared with periods away from work in both types of cases, and the PEF variability is greater in subjects with OA than with WEA.¹³³ However, in clinical practice, the difference in the magnitude of PEF variability does not allow differentiating WEA from OA.

SIC testing can be performed to diagnose OA, with a positive result considered indicative of OA. Although there can be false-negative tests, a negative SIC favors the diagnosis of WEA. In several clinical studies, the definition of OA and WEA relied on the positivity or negativity, respectively, of SIC.⁵² However, those tests are not available in the majority of settings.

An eosinophilic phenotype is more frequently found in subjects with OA compared with WEA. Workers with OA usually show an increase in eosinophilic inflammation when exposed to the agents to which they are sensitized. In contrast, workers with WEA had no increase in eosinophilic inflammation when at work compared with periods away from work or during exposure to the suspected agents in the laboratory.⁵²

Table 72-6 summarizes demographic, clinical, functional, and inflammatory differences between subjects with WEA and subjects with NWRA or OA.

SOCIOECONOMIC IMPACT OF WORK-EXACERBATED ASTHMA

WRA has a major impact on workers and society as a whole. The workers tend to experience asthma symptoms interfering with their work productivity and causing absenteeism. Although there are no current data on absenteeism in subjects with WEA while at work, the cost related to reduced workforce participation, restrictions in job duties, loss of work days (“absenteeism”), or decreased effectiveness while at work (“presenteeism”) is likely to be substantial.

Table 72-6 Characteristics of Work-Exacerbated Asthma (WEA) in Comparison with Non-Work-Related Asthma and Occupational Asthma

Characteristics	Compared with Adults with Non-Work-Related Asthma	Compared with Adults with Occupational Asthma
Gender	Similar ^{135,138} or predominance of men in subjects with WEA ⁸¹	Similar ⁸¹ or greater number of women in subjects with WEA ¹³⁹
Age	Older ^{135,138}	Similar or younger ¹³⁹
Race	More nonwhite ¹³⁵	More nonwhite ¹³⁹
Education	Less ¹³⁵	N/A
Smoking habits	More likely to have smoked cigarettes ¹³⁵	More smokers ⁸¹
Asthma severity	More asthma exacerbations requiring emergency department visits or hospitalizations in workers with WEA, ⁸¹ More days with asthma symptoms, more severe asthma based on self-report ¹³⁵	Same number of asthma exacerbations requiring emergency department visits or hospitalizations ¹³⁷ Greater need of ICS in subjects with WEA ¹³⁷
Functional characteristics	Similar FEV ₁ , PC ₂₀ ⁸¹	Less PEF variability when at work in subjects with WEA compared with OA ¹³³ PC ₂₀ may be lower in subjects with WEA ¹⁴⁰
Airway inflammation	Neutrophilic inflammation inconsistently found depending on the study ^{51,52}	Less likely to have eosinophilic airway inflammation ^{52,137}

ICS, inhaled corticosteroids; OA, occupational asthma; PEF, peak expiratory flow rate.

Presenteeism is the term used to describe employees who are physically present at their jobs but experience decreased productivity because of illness or other barriers to performance. Unproductive workers who are present at work seem to represent even higher costs than those who are absent.¹⁴¹ In addition to the decreased work productivity, the workers have to seek medical care, go to the emergency department, or be hospitalized.

If one examines all of WRA, the 2001 and 2002 data from Breton and colleagues¹⁴² showed that the subjects who reported suffering from WRA in the United States were 4.8 times more likely to report having an asthma exacerbation, 4.8 times more likely to visit the emergency department at least once, and 2.5 times more likely to visit their physician for an asthma exacerbation in the previous 12 months compared with individuals with NWRA. Lemièrre and colleagues⁸¹ confirmed those data showing that 341 subjects with WRA followed in a tertiary Canadian clinic had more visits to the clinic for asthma (4.1 vs. 1.2 $P < 0.05$) and hospitalizations for asthma (0.04 vs. 0.008 $P < 0.05$) during the year preceding their diagnosis than 381 subjects with NWRA. In a recent cohort study of subjects with WRA followed in two Quebec tertiary clinics, Lemièrre and colleagues showed that the health care-related costs were similar between WEA and OA but 10-fold greater than the costs related to NWRA in the year preceding the assessment of those subjects in tertiary clinics.¹³⁷

Although the cost of OA decreased significantly after the diagnosis was made and the patients were removed from exposure, the cost of WEA following the diagnosis did not decrease significantly. In the few studies in which the work disruption of subjects with WEA was evaluated, it was reported to be similar to OA.^{136,140} There is a high rate of unemployment in workers with WEA (30% to 50%),^{140,143} which is equivalent to subjects with OA. Job changes are frequent in subjects affected with WEA. The reduction in earnings seems to be similar in WEA and OA.¹⁴⁰ Overall, WEA exerts a large socioeconomic impact on workers and society by using a large amount of health care resources and inducing substantial disruption of work.

Key Points

- The workplace environment can lead to the development of different types of *work-related asthma* (WRA), including occupational asthma (i.e., asthma caused by work through either immunologic [sensitizer induced] or nonimmunologic [irritant induced] mechanisms) and work-exacerbated asthma (i.e., preexisting or coincident asthma exacerbated by nonspecific stimuli at work).
- WRA represents a significant public health concern due to the high-prevalence, long-term respiratory

health consequences, and socioeconomic consequences for affected workers and society.

- For subjects with sensitizer-induced occupational asthma, the recommended treatment is complete avoidance of the causal agent, although the rate of recovery is low, especially when the diagnosis is delayed.
- The diagnosis of sensitizer-induced occupational asthma should be established with the highest level of accuracy by performing a comprehensive investigation in order to avoid unwarranted removal from exposure.
- Unlike those with sensitizer-induced occupational asthma, subjects with irritant-induced occupational asthma do not develop work-related asthma symptoms after reexposure to low concentrations of the irritant that initiated the symptoms.
- Irritant-induced asthma is characterized by early onset after exposure; however, irritant-induced asthma can also develop insidiously over a few months after a massive exposure to a complex mixture of alkaline dust and combustion products, as shown in the World Trade Center disaster.
- *Work-exacerbated asthma* (WEA) should be suspected in all patients whose asthma is difficult to control and in patients who complain of a worsening of their symptoms or who require an increase of their asthma medication when at work.
- Workers with WEA are often difficult to differentiate from asthmatic subjects with occupational asthma, especially in cases who report a new onset of asthma while in the current workplace.

HARD-METAL DISEASE**SILICON CARBIDE (CARBORUNDUM) PNEUMOCONIOSIS****NEW PNEUMOCONIOSES****INTRODUCTION****DEFINITIONS**

The *Encyclopedia of Occupational Health and Safety* of the International Labour Organization (ILO)¹ defines pneumoconiosis as “the accumulation of dust in the lungs and the tissue reactions to its presence.” The main reaction to mineral dust in the lungs is fibrosis. Not included in the definition of pneumoconiosis are conditions such as asthma, *chronic obstructive pulmonary disease* (COPD), and hypersensitivity pneumonitis, which do not require dust to accumulate in the lungs.

ACCUMULATION OF DUST IN THE LUNG AND TISSUE REACTIONS

The *deposition* of dust in the lungs depends on the size and geometric and aerodynamic properties of the particles. Particle clearance is determined by the mucociliary escalator and cellular mechanisms, in particular, the macrophage (see Chapter 12). Dust *accumulation* in the lungs is determined by deposition and clearance. The biologic *response* depends on the amount and duration of the accumulation and the nature of the dust. Tissue responses to inorganic dusts depend on particle size and the biologic activity of the dust, which in turn depends on its surface chemical and

physical properties.¹ Some dusts, such as coal, are relatively inert and may accumulate in considerable amounts with minimal tissue response; others, in particular silica and asbestos, have potent biologic effects. Parenchymal responses include nodular fibrosis (the classic example is the silicotic nodule), diffuse fibrosis (the classic example is asbestosis), and macule formation with focal emphysema (the classic example is the coal dust macule).² Irregular and mixed fibrotic patterns have been described as a consequence of mixed exposures involving other mineral dusts or fibers in addition to silica dust exposure.³ For any given dust exposure, the severity of the tissue reaction appears to be related to the cumulative lung dust burden.

EXPOSURE-RESPONSE RELATIONSHIPS

In epidemiologic studies, the dust burden in the lung can be assessed only indirectly. However, at an individual level, exposure can be estimated more directly from the job history, from the engineering history of the plant, including the efficiency of dust control, and from environmental measurements.

The demonstration of exposure-response relationships has implications for clinical practice. For instance, a clinical diagnosis of pneumoconiosis is strengthened greatly when there has been exposure to dust levels known to be associated with an increased risk of disease. Although

exposure-response relationships generally describe the events in a work force, there may be heavily exposed individuals who remain unaffected and lightly exposed individuals with disease. Thus, environmental standards such as threshold limit values set by the *American Conference of Government and Industrial Hygienists* (ACGIH) are levels that if respected throughout an individual's working life, are unlikely to be associated with disease. However, dust sampling may be problematic and even in a workplace where average dust concentrations are below the threshold limit value, nearly half the samples exceed this value.⁴ Thus, a clinician should not reject the diagnosis of pneumoconiosis solely on the grounds that exposure was too remote, too short, or in a workplace where the threshold limit value was maintained. The subject in question may be unusually susceptible, may have had an unusual exposure profile, or may retain more dust than others similarly exposed.

CHEST IMAGING

The ILO standard films for the descriptive interpretation of the radiologic appearance of diffuse parenchymal lung disease⁵ were originally developed for epidemiologic studies of occupational lung disease but may also be used for clinical interpretation. The 2011 ILO guidelines accommodate the use of digital images, and a set of standard digital images is available. Apart from improving consistency in the reading of parenchymal disease, which is notoriously subject to reader variability, they enable the clinician to set an individual case in the context of the available epidemiologic information.⁵ Small opacities in the parenchyma are classified by shape and size: p, q, or r for rounded opacities (diameter, <1.5 mm, 1.5 to 3 mm, or >3 mm, respectively) and s, t, or u for irregular opacities (width, <1.5 mm, 1.5 to 3 mm, or >3 mm, respectively). Profusion category (or concentration) is read on a 12-point scale (0/–, 0/0, 0/1, up to 3/2, 3/3, and 3/+) in comparison with the standard radiographs. Large opacities are classified as category A (for one or more such opacities with a diameter > 1 cm but not exceeding a combined diameter of 5 cm), category B (one or more opacities > 5 cm in diameter and whose combined area does not exceed one upper zone), and category C (>B). Provision is made to grade pleural thickening for width ($a \leq 5$ mm, $b > 5$ mm but < 10 mm, and $c \geq 10$ mm) and extent (1 = up to one quarter, 2 = one quarter to one half, and 3 = over one half of the lateral chest wall). The extent of pleural calcification is also graded, and there are provisions for comment on other features.

In the United States, the *National Institute of Occupational Safety and Health* (NIOSH) administers the National Coal Workers' Health Surveillance Program, which provides coal miners with the opportunity of a periodic medical examination. The program incorporates quality control in terms of radiographic technique and reading procedures using the ILO classification and reader training. This involves training seminars for physicians who may qualify as "A" readers (i.e., attended the seminars) or "B" readers, who passed a comprehensive examination on the basis of 120 radiographs read into the ILO classification.

Conventional chest radiographs or digital images are the cornerstone of surveillance for pneumoconiosis in the

workplace. *Computed tomography* (CT) and *high-resolution computed tomography* (HRCT) have revolutionized clinical case evaluation. CT and HRCT are able to characterize lung and pleural lesions, as well as their extent and confluence, and are considerably more sensitive than the conventional chest radiograph. The role of magnetic resonance imaging in the diagnosis of pneumoconiosis is limited, but the technique has been used to differentiate between pleural plaques and mesothelioma.⁶ *Positron emission tomography* (PET) scans have been used to detect pulmonary neoplasms in the presence of pneumoconiosis,⁷ but increased metabolic activity in lesions of progressive massive fibrosis,⁸ in benign lung nodules in coal workers' pneumoconiosis,⁹ and in mediastinal nodes in patients with pneumoconiosis¹⁰ limit the usefulness of the technique. The chest radiograph remains the accepted method for surveillance and assessment because of its wide availability, acceptable cost and radiation dose, and the standardization of its reading.

CLINICAL ISSUES, LUNG FUNCTION, AND PRINCIPLES OF MANAGEMENT

The clinician is faced with two main tasks when evaluating a case of suspected pneumoconiosis. *First*, the clinician must assess the nature of the disease process, including its site (airways or pulmonary parenchyma or pleura) and its extent, as well as to determine whether it has decreased the individual's performance in particular for his or her current job (evidence of impairment or disability). Assessment of impairment is based on symptoms and measurements of pulmonary function at rest and during exercise where indicated (see Chapters 25 and 26). Pneumoconiosis may be associated with apparently normal lung function or with a predominantly obstructive, restrictive, or mixed pattern of dysfunction. In the individual case, interpretation of results in terms of lung function profiles is usually done by the use of reference or predicted values. These may, however, be misleading given that those who undertake dusty occupations on average have higher initial spirometry and lung volumes than the general population, on whom most predicted values are based.¹¹ Thus, it is not appropriate to minimize the functional significance of pneumoconiosis on the grounds of apparently normal lung function. Assessment of disability is made in the wider context of whether the subject is fit for his or her job and, thus, requires expert knowledge of the job content.

Second, the clinician needs to determine whether there has been environmental or occupational exposure of duration, intensity, and character sufficient to account in full or in part for the patient's present condition. For this task, the key tool is the occupational history, which can be completed with the addition of the often extensive knowledge that the worker can provide concerning his or her occupations, the materials handled, and the processes involved. Because pneumoconiosis is a reaction to retained dust, it may appear and progress after exposure has ceased¹²; hence, the importance of a complete exposure history, including student summer jobs, military service, and short-term jobs. In addition, in industrialized countries, between 25% and 60% of men and up to 30% of women report exposure to dust or fumes at work,¹³ further testimony to the fact that an occupational history is as essential as the smoking history in the

Figure 73-1 The putative agent in the lung tissue in four cases of pneumoconiosis. **A**, Typical asbestos body (arrow) in the lung of a crocidolite asbestos miner with asbestosis, from South Africa. **B**, Lung digest from the case of a 67-year-old long-term chrysotile miner with asbestosis from the Thetford area, photographed on a filter of pore diameter 0.2 mm (pores are evident as small punched-out areas in the photograph). The thin fibers were identified as chrysotile using morphologic criteria and energy-dispersive x-ray spectrometry (EDS). The thick fibers were identified as tremolite by EDS. In this mining area, there is a small amount of tremolite in the mined ore that accumulates preferentially in the lung tissue.¹ Amphiboles such as crocidolite, amosite, and tremolite most frequently form the core of asbestos bodies. For each asbestos body found in lung tissue, the number of uncoated fibers is at least several orders of magnitude greater. **C**, Lung section from a 53-year-old man who worked in a mica milling factory. The mica (arrows) appears as birefringent (bright white) elongated particles. **D**, Lung from a foundry worker shows amorphous black carbon particles and a cluster of rounded iron-coated particles (arrow). Particle clusters like this are frequently seen in the lung sections of welders and foundry workers who have had exposure to iron dusts and fumes. Fraser, Department of Pathology, and Dr. Patrick Sébastien, formerly of the School of Occupational Health, McGill University, Montreal.)

practice of respiratory medicine. On occasions, it may be necessary to establish occupational exposure on the basis of analysis of biologic material (sputum, *bronchoalveolar lavage* [BAL], transbronchial or open-lung biopsy specimen) for the putative dust or its breakdown products. This is particularly so in cases in which the exposure is remote and the exposure history incomplete or unreliable. **Figure 73-1** presents examples of cases in which the putative dust was demonstrated in the pathologic specimens. The case record described in the legend for **Figure 73-9** is an example of the use of lung dust burden measurements in establishing attributability.

Tuberculosis was a common complication of pneumoconiosis in the early part of the 20th century. Although now relatively rare in industrialized countries, tuberculosis remains an important issue in industrializing countries and has increased dramatically, especially in South Africa, in response to the *human immunodeficiency virus* (HIV) epidemic.¹⁴

Pneumoconiosis does not regress and may appear and progress only after work exposure ceases.¹² In general, the worker with pneumoconiosis should have no further occupational dust exposure.

The physician has the legal responsibility to report all cases of pneumoconiosis.¹² The diagnosis of pneumoconiosis reflects a failure of environmental controls in the work-

place that may require intervention by an appropriate authority. There are differences in disease notification practice and compensation legislation among states and among countries, and physicians should be aware of the appropriate procedures in the location of their practice.

EPIDEMIOLOGY AND IMPLICATIONS FOR CLINICAL PRACTICE

Information on the distribution of these diseases within and between work forces and the factors that influence distribution provides the scientific base that the physician uses to reach a diagnosis, set prognosis, and plan management. Thus, knowledge of pneumoconiosis rates in the industries located in the local area assists the physician in diagnosis. Likewise, determining prognosis depends on work force-based information, on knowing which factors influence disease progression favorably and unfavorably, and the likely effect of further exposure even at low levels.

In the discussion that follows, the various types of pneumoconioses are considered separately with respect to occupations at risk, pathophysiology and epidemiology, as well as the clinical issues of diagnosis, prognosis, and management. On all continents and in many countries, a substantial proportion of individuals is exposed to dust at work and therefore potentially at risk for pneumoconiosis.¹³

Table 73-1 Industries and Occupations at Risk for Silicosis

Industries with Examples	Occupations Implicated
MINING, TUNNELING, AND EXCAVATING	
Underground: gold, copper, iron, tin, uranium, civil engineering projects	Miner, driller, tunneler, developer, stoper*
Surface: coal, iron, excavation of foundations	Mobile rig drill operator
Quarrying	
Granite, sandstone, slate, sand, chinastone/clay	Driller, hammerer, digger
Stonework	
Granite sheds, monumental masonry	Cutter, dresser, driller, polisher, grinder, mason
FOUNDRIES	
Ferrous and nonferrous metals	Molder, knockout man, fettler, [†] coremaker, caster
ABRASIVES	
Production: silica flour, metal polish, and sandpapers, fillers in paint, rubber, and plastics	Crusher, pulverizer, and mixer; workers in the manufacture of abrasives
Sandblasting: oil rigs, tombstones, denim	Operators of high-speed jets
CERAMICS	
Manufacture of pottery, stoneware, refractory bricks for ovens and kilns	Workers at any stage of process if products are dry
OTHERS	
Glass making, boiler scaling, traditional crafts, stone grinders, gemstone workers, dental technicians, concrete reconstruction	

*Stoper, a miner who works in a steplike excavation made in a step vein in a mine.

[†]Fettler, a worker who cleans the machines in the mill and sands and grinds imperfections from metal castings.

Lists of occupations and jobs at risk are never exhaustive (Table 73-1) but are a guide for use in general office practice. For those in occupational health or occupational medicine practice, reference should be made to one of the more specialized texts that describe the occupations at risk in greater detail.

SILICOSIS

DEFINITION

Silicosis is a fibrotic lung disease attributable to the inhalation of crystalline silica usually in the form of quartz and, less commonly, as cristobalite and tridymite.^{1,15,16} Amorphous silica is relatively nontoxic; silicates such as asbestos, mica, and talc evoke a different type of pulmonary response and are considered separately.

INDUSTRIES AND OCCUPATIONS STILL AT RISK

Silicosis is an ancient disease that continues to be a major disease worldwide in men and women exposed to silica dust in a variety of occupations.^{1,17} Table 73-1 provides some common examples of industries in which workers are at risk for silica exposure. Construction, surface, and under-

ground rock drilling have all been subjects of Alert documents from NIOSH. Foundries are also a main source of silica dust. More recent reports have shown a silicosis risk for workers involved with the repair, rehabilitation, or demolition of concrete structures¹⁸ including roads.¹⁹ Less common occupations associated with silicosis include workers producing stressed denim by sandblasting,²⁰ stone carvers,²¹ granite countertop manufacturers,^{22,22a} dental technicians,^{22b,22c} and jewelers using chalk molds.²³ Many of the current cases of silicosis come from industries using relatively new technology that, if unaccompanied by modern controls, may result in exposures to finer dust particles than in traditional industries and jobs. Many “new” types of pneumoconiosis often turn out to be silicosis in an industry not previously thought to be at risk or a mixed dust pneumoconiosis in which silica is implicated with other dusts.

Silicosis is often the result of exposure in the remote past and not in the current workplace. The risks for silicosis depend on the levels of exposure and, although this can be controlled, there is evidence that dust levels may be monitored inappropriately and that the sampling accuracy may be poor in many workplaces.²⁴

Outbreaks of silicosis and death from the disease continue to be reported worldwide,^{12,21,24} even in countries with developed legislative systems and environmental surveillance programs, such as the United States,²⁵ Canada,²⁶ Europe,²⁷ and South Africa.²⁸ U.S. data show that the rate of decline in deaths from silicosis has lessened after 1995 with an increased proportion of deaths in the age group younger than 45 years. These data indicate “that intense overexposures to respirable crystalline silica continue to occur despite the existence of legally enforceable limits.”¹⁷ In China 23 million workers are exposed to silica, while in the United States, NIOSH has estimated that at least 1.7 million workers are exposed to silica, of whom between 1500 and 2360 will develop silicosis each year. Cases of silicosis have also been reported following general environmental exposure^{29,30} and in agricultural workers.^{31,32}

PATHOLOGY

Three clinicopathologic types of silicosis have been described: *chronic silicosis*, which typically follows exposure, measured in decades rather than years, to respirable dust usually containing less than 30% quartz; *accelerated silicosis*, which follows shorter, heavier exposure; and *acute silicosis* (silicoproteinosis), which follows intense exposure to fine dust of high silica content, such as that found in sandblasting industries, for periods measured in months rather than years.^{2,15}

Chronic silicosis is the most common form of the disease. The hallmark of chronic silicosis is the silicotic nodule, one of the few agent-specific lesions in pathology (Fig. 73-2A and B; eFig. 73-1). Silicotic nodules develop first in the hilar lymph nodes³³ and may be confined to this area; they may become encased in calcification and impinge on or erode into airways. The disease process next involves the lung parenchyma. It is usually bilateral, predominantly involving the upper zones.

In accelerated silicosis, the changes are similar to those seen in chronic silicosis. However, the nodules develop

Figure 73-2 Pathologic lesions of chronic silicosis. **A**, Silicotic nodule characterized by a central zone of a cellular hyalinized collagen with a whorled appearance and a peripheral zone of dust-laden macrophages. **B**, Silicotic nodule at higher magnification to show these characteristics to better advantage. **C**, Progressive massive fibrosis shows confluent silicotic nodules and aggregates of dust-laden macrophages (arrows). **D**, Mineral dust small airway disease characterized by peribronchiolar fibrous tissue containing a moderate amount of pigment (arrows). (Courtesy National Institute for Occupational Health, South Africa.)

sooner (after 3 to 10 years of exposure), may be more widely distributed in the lung, and are more cellular than fibrotic.

With disease progression in both chronic and accelerated silicosis, the nodules may become confluent, leading to the development of *progressive massive fibrosis* (PMF) (see Fig. 73-2C), also known as *complicated silicosis*. These lesions, which are at least 1 cm in diameter (and often larger), usually involve the upper lobes. They tend to obliterate lung structure and may cavitate, which may be an indication of tuberculosis.² *Rheumatoid nodules* may also develop in the setting of silicosis and may be seen in subjects with rheumatoid arthritis or high levels of circulating rheumatoid factor.² There may be silicotic nodules in the background. Rheumatoid nodules are less frequently associated with silica than with coal dust exposure (see subsequent discussion).

Acute silicosis shows all the features of pulmonary alveolar proteinosis (see Chapter 70). Silica particles and various biomarkers of tissue reaction can be identified in the proteinaceous material from the alveolar spaces and in lavage material.

The lungs of exposed individuals, whether or not they show silicosis, also may demonstrate the features of other diseases associated with occupational dust exposure, such as chronic bronchitis and emphysema. The pathologic features are similar whether associated with occupational exposure to dusts and fumes encountered in the workplace or with exposure to tobacco smoke. Small airway abnormalities, including fibrosis and pigmentation of respiratory bronchioles (see Fig. 73-2D), are seen in association with exposures to a variety of mineral dusts including those responsible for silicosis.³⁴

Silicotic nodules may also develop in the cervical and abdominal lymph nodes and, occasionally, in the liver, spleen, and bone marrow.¹²

PATHOGENESIS

The pathogenicity of silica dust is dependent on the physical, mechanical, and chemical properties of the particles. A review of this topic summarizes the processes whereby silica produces inflammation and fibrogenesis in the lung.³⁵ However, the cellular mechanisms that initiate and drive the process of inflammation and fibrosis are not fully understood. There is agreement that freshly fractured silica, such as that generated during sandblasting, is more toxic to the alveolar macrophages than is “aged” silica, presumably because of its increased redox potential. Other minerals, particularly clay components, may adhere to the surfaces of silica particles, producing “coated” silica that is less toxic than uncoated silica dust. This may explain the relatively nonfibrogenic response to silica in coal and hematite miners and the observation that the incidence of silicosis is decreased by concomitant exposure to other dusts. Silica particles smaller than 5 μm reach the lower respiratory tract and may enter the alveoli. The intensity of the exposure determines the nature of the lung injury.

Tumor necrosis factor- α (TNF- α) and *interleukin 1* (IL-1) play an important role in the initiation of silicosis, and experimental inhibition of these cytokines has been shown to prevent silicosis. Growth factors, including *transforming growth factor- β* (TGF- β), are important in fibrogenesis (and also have been implicated in carcinogenesis) in association with silica.^{36,37} A review describes the immune response to

silica in more detail and the role of innate and adaptive immunity.³⁸ Although the major determinant of silicosis is the level of exposure to silica-containing dust, individual susceptibility to the disease may play a role in its development and severity.^{39,40}

EPIDEMIOLOGY: SECULAR TRENDS AND THEIR IMPLICATIONS FOR THE CLINICIAN

Over the course of the 20th century, silicosis changed from a rapidly fatal disease to an indolent and disabling disorder. Reasons include improved environmental controls, falling rates of tuberculosis, and the advent of drug therapy for tuberculosis. Nevertheless, there is still well-warranted concern that this avoidable disease will remain a significant cause of morbidity¹² and mortality in the 21st century.^{41,42} The prevalence of silicosis is difficult to estimate, given the large number of industries at risk (see Table 73-1), the transient labor force in industrializing and industrialized countries, and the frequent appearance (and progression) of disease after the worker has left the work force.^{43,44} Despite the progress made, silicosis has been reported in workers from a variety of industries in persons starting work after 1970, and reported cases have been estimated to under-represent the total cases of silicosis substantially.⁴⁵ In calculating an individual's risk for silicosis, duration and intensity of exposure are of primary interest but peak exposure also may be important.⁴⁶ The physician should never dismiss the diagnosis of silicosis when that diagnosis is suggested by clinical and radiologic features, even when exposure appears to have been insignificant or in an occupation not known to be associated with silicosis.

TUBERCULOSIS

The association between silicosis and tuberculosis has long been recognized. Rates for active tuberculosis in silicotic subjects range from two- to thirty-fold more than those in the same workforce without silicosis.⁴⁷ Factors that influence the development of tuberculosis in the subject with silicosis include the severity and type of disease (the risk is considerably higher in patients with acute and accelerated silicosis),¹⁵ the prevalence of tuberculosis in the population from which the work force was drawn, as well as their age, general health, and HIV status.⁴⁷⁻⁴⁹ Exposure to silica, without silicosis, may also predispose individuals to tuberculosis.^{47,48}

Tuberculosis is characterized by necrotizing epithelioid granulomas. These are never seen with silicosis alone. Although *Mycobacterium tuberculosis* is the usual organism, nontuberculous mycobacteria account for a large proportion of the mycobacterial disease in populations in which nontuberculous mycobacterial disease is common.^{12,50} Smoking has been shown to increase the risk for the development of tuberculosis in those with silicosis.⁵¹ There is some evidence to suggest that those with silicosis are also at risk for fungal infections.⁵²

AIRFLOW OBSTRUCTION AND CHRONIC BRONCHITIS

COPD and chronic bronchitis are common manifestations of long-term occupational exposure to environments con-

taminated by silica dust and can develop in silica-exposed individuals with or without silicosis.^{12,53-55} Small airway abnormalities, including fibrosis and pigmentation of respiratory bronchioles (see Fig. 73-2D), are also seen in association with exposures to a variety of mineral dusts including silica.³⁴ In South African gold miners, the estimated *additional* loss of lung function attributable to mine dust exposure without invoking silicosis or tuberculosis is an average of 208 mL of forced vital capacity over a 30-year working life (in excess of the expected loss of 400 to 500 mL over 30 years in normal men with age).⁵⁶ In a study of adolescents and young adults working in a stone-crushing plant, lung function changes were interpreted as evidence for impaired lung growth that was attributed to their high respirable crystalline silica exposure.⁵⁷ Smoking can potentiate the effect of silica dust on airflow obstruction.⁵⁴

CONNECTIVE TISSUE DISEASES, RENAL DISEASE, AND CARDIOVASCULAR DISEASE

Associations have been reported between exposure to silica and certain connective tissue diseases including progressive systemic sclerosis, systemic lupus erythematosus, and as previously mentioned, rheumatoid arthritis.^{12,58} Epidemiologic evidence indicates that the prevalence of rheumatoid arthritis is increased in those with exposure to silica and in those with silicosis.⁵⁹ Systemic sclerosis has been shown to be associated with silicosis⁵⁹ but may also be associated with silica dust exposure without silicosis.¹² The evidence for an association between lupus erythematosus and silicosis is strongest for acute or accelerated silicosis but is inconclusive for chronic silicosis.^{12,59}

Renal disease has been reported in silica-exposed workers. Some studies have implicated an immune complex glomerulitis or a direct toxic effect of silica.^{12,59,60} Silicosis has been linked with *antineutrophil cytoplasmic antibody* (ANCA) positivity and possibly with vasculitis.^{58,61}

Cardiovascular disease may also be associated with silica exposure. A recent report of a cohort of 74,040 silica-exposed workers found an increased mortality compared with nonexposed workers; cardiovascular disease was the major cause of death.⁶²

LUNG CANCER

The association between silicosis and lung cancer has been difficult to establish because of the high prevalence of smoking in silica-exposed workers and because of frequent concomitant radon exposure.¹² Studies of non-radon-exposed, nonsmoking workers with silicosis suggest a clear relationship between silicosis and lung cancer, but there remains some doubt as to whether silica exposure, in the absence of silicosis, carries an increased risk for lung cancer.^{12,59,62-65,65a}

CLINICAL FEATURES

The symptoms and signs of chronic silicosis may be minimal. The main symptom is breathlessness but, in chronic silicosis, in the absence of other respiratory disease, even this symptom may be absent. It is not unusual for a patient with chronic silicosis to present without symptoms

for assessment of an abnormal chest radiograph. The appearance of breathlessness may mark the development of a complication such as PMF or tuberculosis or may reflect associated airway disease. Cough and sputum production are common symptoms and usually relate to chronic bronchitis but may reflect the development of tuberculosis or lung cancer. Chest pain is not a feature of silicosis nor are systemic symptoms such as fever and weight loss, which should be attributed to tuberculosis or lung cancer until proved otherwise. Clubbing is also not a feature of silicosis and should raise concern about lung cancer.

In accelerated and acute silicosis, the time scale of symptom evolution is in years or months rather than in decades. In acute silicosis, breathlessness may become disabling within months, followed by impaired gas exchange and respiratory failure.

RADIOGRAPHIC FEATURES

Uncomplicated silicosis is characterized by the presence of small rounded opacities on the chest radiograph,^{1,15} as

graded in the ILO classification (as described previously).⁵ In general, there is a good correlation among dust exposure, the amount of dust in the lungs, the lung pathology, and the chest radiograph.⁶⁶ However, occasionally, even advanced silicosis, determined by histology, may not be apparent on a chest radiograph.⁶⁷

Silicotic nodules are usually symmetrically distributed and tend to appear first in the upper zones (Fig. 73-3), later, although not invariably, involving other zones (eFig. 73-2). Enlargement of the hilar nodes may precede the development of the parenchymal lesions. Eggshell calcification, when present, is strongly suggestive, although not pathognomonic, of silicosis (Fig. 73-4; see also Fig. 73-3, eFig. 73-3).

PMF is characterized by the coalescence of small rounded opacities to form larger lesions (eFig. 73-4A); they are graded on the ILO scale according to size and extent (categories A to C). CT assessment is superior to the chest radiograph in not only assessing the presence and extent of silicotic nodulation but also revealing early conglomeration (eFig. 73-4-E; Videos 73-1 and 73-2).⁶⁸ With time, the mass

Figure 73-3 Radiographic patterns of silicosis. **A**, Posteroanterior chest radiograph shows predominantly upper zone but, atypically, asymmetrical nodularity (arrowheads). **B**, Detail image shows the “eggshell” calcification of the hilar lymph nodes (arrowheads). This latter feature strongly suggests that the nodular opacities in the lung parenchyma on this chest radiograph represent silicosis, notwithstanding the patient’s history of 30 years of underground work in a coal mine. **C**, Lateral view shows the eggshell calcification (arrowheads) and also a larger and probably calcified nodule situated anteriorly and a small calcified parenchymal lung nodule (arrow). These latter features are compatible with a healed primary tuberculous focus and, if this is supported by a positive test for tuberculosis, a course of treatment for latent tuberculosis infection should be offered. (Courtesy Dr. J. H. M. MacGregor, University of Calgary.)

Figure 73-4 Progressive massive fibrosis. **A**, Posteroanterior radiograph shows features of progressive massive fibrosis (PMF) with “eggshell” calcification of the mediastinal and peribronchial nodes (arrowheads), in keeping with complicated silicosis, in a man who had shoveled sand in a glass factory. **B**, Detail view shows the PMF with a background of smaller nodules and the eggshell calcification. (Courtesy Dr. J. H. M. MacGregor, University of Calgary.)

lesions tend to contract, usually to the upper lobes, leaving hypertranslucent zones at their margins (eFigs. 73-5 and 73-6) and often at the lung bases. In this process, small rounded opacities, previously evident, may disappear, resulting in a picture that must be distinguished from tuberculosis. The rapid development of several large lesions suggests rheumatoid silicosis, but new lesions, especially if cavitated, should be regarded as evidence of mycobacterial disease. Acute silicosis is characterized radiologically by diffuse changes that usually display an air space and interstitial pattern rather than the usual nodularity.⁶⁹

LUNG FUNCTION

The lung function profile is determined by the extent of silicosis, as well as associated or concomitant airway and vascular changes. In chronic silicosis, spirometric tests (*forced expiratory volume in 1 second* [FEV₁], FEV₁/forced vital capacity [FVC]) usually reflect airflow limitation.¹² Reduction in *diffusing capacity of carbon monoxide* (DL_{CO}) is generally apparent in more advanced chronic silicosis and probably reflects associated emphysema.⁷⁰

In the accelerated and acute forms, functional changes are more marked and progression is more rapid. In acute silicosis, lung function shows a restrictive defect and impairment of gas exchange, which leads to respiratory failure.

DIAGNOSIS AND COMPLICATIONS

Silicosis is diagnosed on the basis of a history of exposure and the characteristic radiographic changes.¹⁵ Problems arise when the history of exposure is remote, forgotten, or missed or has taken place outside a recognized occupation. Occasionally, the radiologic features are unusual; examples include the presence of hilar lymphadenopathy or of large lung opacities in the absence of typical small nodules. Detection of silica in BAL material may suggest the diagnosis. Lung biopsy may be necessary to distinguish progressive massive fibrosis or other atypical features from lung cancer, tuberculosis, and other diagnoses. Biopsy material should be submitted for microanalysis for dust including silica.

Less common complications include cor pulmonale, spontaneous pneumothorax, broncholithiasis, and tracheobronchial obstruction from enlarged calcified hilar nodes.¹⁵ The diagnosis of active tuberculosis in the silicotic subject may be more difficult than in the nonsilicotic subject but, in general, a good sample of sputum or sputum induced by nebulized hypertonic saline sent for mycobacterial culture provides the diagnosis. The presence of cough, hemoptysis, weight loss, fever, or any new radiologic feature (eFig. 73-7) should be pursued with culture of sputum or BAL fluid or with culture and histologic examination of tissue. In many instances, it is the chest imaging rather than the clinical features that gives the first indication of tuberculosis in the presence of silicosis (see eFig. 73-7,  Video 73-3), but it should be noted that those with silicosis are also at risk for extrapulmonary tuberculosis.⁴⁷

MANAGEMENT AND CONTROL

Once established, the fibrotic process of chronic silicosis is thought to be irreversible. Management of the individual

case is thus directed toward preventing progression and the development of complicated disease. A change in occupation to an environment free of silica-containing dust should be advised. The disease will generally progress even without further exposure,^{43,44} but the rate of deterioration may be reduced.

Interventions to interrupt the inflammatory process that leads to chronic silicosis including the inhalation of aluminum or polyvinylpyridine-N-oxide and oral tetrandrine have not been shown to be successful. There is currently interest in the use of lung lavage to remove silica from the lung, but a favorable impact on progression of acute or chronic silicosis has not been demonstrated. Treatment of all forms of silicosis should be directed toward control of mycobacterial disease. This is especially true for acute and accelerated silicosis and silicosis in workers with HIV infection.^{15,49} All subjects with silicosis should have a tuberculin skin test or an *interferon-γ* (IFN-γ) release assay⁷¹ and, if positive in the absence of evidence of tuberculosis, be offered treatment for latent tuberculosis infection (see Chapter 35).

The interaction between silica exposure and smoking in the development of COPD, tuberculosis,⁵¹ and lung cancer makes it important to implement smoking-cessation programs in the workplace.

Because acute and accelerated silicosis carry such a poor prognosis and tend to arise in younger subjects,⁷² consideration should be given for lung transplantation in such cases (see Chapter 106).

The most important aspect of the management of silicosis relates to its prevention. To achieve this, a sustained effort must be made to increase awareness of silicosis. Recent deaths from silicosis in younger subjects in the United States have been reported after exposure in the construction and manufacturing sectors, with none from mining.⁷² Deaths of young people sandblasting denim²⁰ are a reminder that there is often a lack of awareness of the hazards of silica outside the traditional occupations associated with silicosis.

COAL WORKERS' PNEUMOCONIOSIS

DEFINITION AND OCCUPATIONS AT RISK

Coal workers' pneumoconiosis (CWP) is a distinct pathologic entity resulting from the deposition of coal dust in the lungs.^{1,2,4} The tissue reactions to deposits of dust include the *coal macule* and *coal nodule* (simple CWP) and PMF (complicated CWP)² (Fig. 73-5).

The main occupation at risk for CWP is coal mining, an industry that in the 1970s employed approximately 250,000 people in the United Kingdom and a comparable number in Western Europe.¹³ Approximately 175,000 coal miners were employed in the United States in 1986; since then, there had been a steady decrease in the number to approximately 80,000 in 1999 but, in 2011, the number increased to 143,437.⁷³ It has been estimated that there are 6 million coal miners in China. Coal is also mined in Eastern Europe, India, and on the African, Australian, and South American continents. With mechanization, output and

Figure 73-5 Pathologic lesions of coal workers' pneumoconiosis: examples from South African coal miners. **A**, Coal macule shows an aggregation of dust and dust-laden macrophages in the wall of a distal airway in which reticulin and a few collagen fibers were demonstrated. **B**, Coal nodule consists of dust and dust-laden macrophages and dense, irregular depositions of collagen (arrows). This lesion would be palpable. Associated focal emphysema was also evident. **C**, Progressive massive fibrosis with coalescence of nodules and dense collagen deposition. Figure 73-6 Progressive massive fibrosis (PMF). **A**, Chest radiograph shows PMF with evidence of cavitation with an air-fluid level in the right lower lung (arrow). This image represents complicated coal workers' pneumoconiosis. **B**, Chest CT shows the background nodularity and the lesions of PMF with cavitation on the right. (Courtesy Dr. J. H. M. MacGregor, University of Calgary.)

potential for dust exposure have increased. Former and current coal workers are likely to continue to be seen with CWP. Surface coal miners are also at risk for pneumoconiosis but are not always included in surveillance programs.⁷⁴

Coal mine dust contains a variable amount of quartz depending on the nature of ore-bearing rock, the size of the coal seam, and the processes used to mine the seam (including the degree of mechanization). Coal miners may also develop silicotic nodules when the coal seams are in hard rock. Silicosis is more common in mines with a high grade or *rank* of coal (see later in “*Pathogenesis*”) and in workers such as roof bolters who work outside of the coal seams.^{2,4} Current evidence shows that coal mining, even in the absence of CWP, is associated with chronic bronchitis, chronic airflow limitation,^{4,75,76} and emphysema.^{2,4,77}

Other occupations at risk for exposure to coal or carbon dust include coal trimming (which involves loading and stowing coal in stores or ships' holds), the mining and milling of graphite in carbon plants, the manufacture of carbon electrodes, and the manufacture and use of carbon black.

PATHOLOGY

The primary lesion in CWP is the coal macule, which can be seen (although not palpated) on macroscopic examination as a small (≤ 4 mm) pigmented lesion, distributed

initially in the upper lobes, although the lower lobes may subsequently become involved.² On microscopic examination, the coal macule consists of a stellate aggregation of dust and dust-laden macrophages around respiratory bronchioles, with reticulin fibers and a variable amount of collagen (see Fig. 73-5).² Focal emphysema, a form of centriacinar emphysema, forms within and around the coal macule, and together they form the characteristic lesion of CWP.² The coal nodule is a palpable lesion that, in addition to dust-laden macrophages and reticulin, contains a substantial number of haphazardly arranged collagen fibers.² Coal nodules, which result from exposure to coal dust admixed with silica, are usually present in association with coal macules.¹ Classic silicotic lesions are seen in approximately 12% of U.S. coal miners² and form when lung dust residue contains 18% or more quartz. Other features include subpleural dust deposits, enlargement of the hilar and mediastinal nodes and, on occasion, tattooing of the parietal pleural lymphatic channels by coal dust.

PMF (complicated CWP) is defined as a fibrotic pneumoconiotic lesion 1 cm or greater in diameter. These bulky, often irregular, well-defined, heavily pigmented rubbery black tissue masses usually appear in a background of severe simple CWP. PMF usually develops in the posterior segment of the upper lobes or apical segments of the lower lobes and is typically bilateral (Figs. 73-6 and 73-7). Microscopically, the lesions contain the same elements as the coal nodule (see Fig. 73-5C). They may impinge on and

Figure 73-7 Progressive massive fibrosis (PMF). **A**, Whole-lung section of a 71-year-old Appalachian coal miner. The miner was a nonsmoker and had worked for 28 years underground, primarily at face work (directly involved in mining at the face surface of the mine). The midsagittal section of the left lung shows massive lesions in the superior segment of the lower lobe and in the central area of the upper lobe (arrows). PMF is seen against a background of simple nodular and macular coal workers' pneumoconiosis. In several areas, there is evidence of coalescence of nodules. There is mild focal emphysema associated with the coal dust macules. **B**, Chest radiograph shows features of PMF against a background of nodularity. The mass lesion on the right shows the propensity of PMF to move toward the hilum. The opacities are somewhat atypical given their predominantly lower lung location. (Case from the National Institute of Occupational Safety and Health W. Laqueur collection, courtesy Drs. V. Vallyathan and F. H. Y. Green.)

obliterate airways and vessels and cross interlobar fissures. Cavitation is not uncommon, probably as a consequence of ischemic necrosis, given that vascular obliteration is common within areas of PMF.

Rheumatoid pneumoconiosis,² one variant of which is called Caplan syndrome, is a form of CWP associated with rheumatoid arthritis or a rheumatoid diathesis. It is characterized by nodules that are larger than coal nodules and have smoother borders. Pigmentation is arranged in concentric laminations and, relative to PMF lesions, they contain little dust. These lesions may cavitate or calcify. The microscopic features are similar to those described for the rheumatoid silicotic lesion (see earlier discussion under the "Pathology" of "Silicosis"). Active areas in the nodules contain dust-laden macrophages, lymphocytes, polymorphonuclear leukocytes, and plasma cells. When activity ceases, they may collapse or calcify. Rheumatoid pneumoconiosis lesions were originally described in Welsh coal miners and are reported in Belgian coal miners but are uncommon in North American coal miners.

Diffuse interstitial fibrosis has also been reported in coal miners; the fibrosis may contain black carbon pigment and may appear similar to the *usual interstitial pneumonia* (UIP) pattern. However, it has a relatively benign clinical course compared with that of the same condition in the general population.²

PATHOGENESIS

The risk for CWP increases with the intensity and duration of exposure to coal dust. The effect of coal on the lung is

also related to its rank, a measure of the degree of metamorphosis and which is based on its carbon content. Anthracite ranks highest (93% carbon), followed by bituminous, sub bituminous, and lignite, with the lowest carbon content (60% to 70%).^{2,4} In epidemiologic studies, CWP is more common in mines of high-rank coal than in those of low-rank coal. This may relate to the greater relative surface area of the coal dust particles, higher surface free radicals, and more frequent presence of silica in the high-rank, rather than the low-rank, coal.^{2,4} The coal dust macule and nodule are ascribed to the accumulation of large amounts of relatively inert dust in the lung. As the lung burden of dust increases, alveolar macrophages are activated and reactive oxygen species are released. These in turn trigger the release of cytokines, including interleukins and TNF, which set in motion the processes of inflammation and fibrogenesis that are responsible for the development of pneumoconiosis and also trigger the release of proteases, which contribute to the associated emphysema. The fibrosis, however, is considerably less intense and extensive than that evoked by the more bioactive dusts, such as silica and asbestos.

Although the exact pathogenic mechanisms underlying the development of PMF remain in doubt, these lesions are thought to relate to the amount of coal dust accumulated in the lung, the proportion of inhaled silica in the dust and its surface bioactivity, individual immunologic and genetic factors, and whether tuberculosis is present.^{2,4,40} Of these factors, the total dust burden appears to be the most important. In addition, there are striking differences in rates of simple pneumoconiosis and PMF among different coal pits,

mining areas, and countries,^{2,4,40} suggesting that other characteristics of the dust particles, including their shape, size, composition, bioactivity, and durability in lung tissue, also contribute to the risk of developing CWP and PMF.

EPIDEMIOLOGY AND NATURAL HISTORY

Early studies of coal miners suggested that the occupation of coal mining and even the presence of CWP were not associated with higher mortality rates. These studies probably did not take the healthy worker effect into account, and more recent studies have shown that exposure to coal dust is associated with increased mortality.^{78,79} Overall, in the United States, the mortality associated with CWP decreased by 36% from 1982 to 2000 compared with 1968 to 1981,⁸⁰ but more recent data showed an increase in years of potential life lost before the age of 65 years since 2002.⁸¹

Although the rates of CWP had been falling steadily in the United States and Europe, new cases continue to be detected^{1,25,73,82} and the diseases associated with coal dust have shown an increase since 1995 notwithstanding apparent adherence to the current dust standard.^{73,83-85} The presence of PMF is associated with more severe adverse effects on the health and life expectancy of coal miners than those of simple CWP, and recent data show a sharp increase in the finding of PMF in U.S. underground coal miners.^{85a} Risk factors for PMF include the presence and stage of CWP, the intensity of dust exposure, and the age of the subject.⁸⁶ The role of silica in the development of PMF is controversial but is generally believed to be important.^{2,4,87} A study of coal miners with rapidly progressive CWP suggests that silica exposure might be a marker for the development of PMF. Risk factors for rapid progression of CWP included working at the face in smaller mines, younger age, and mining in eastern Kentucky and western Virginia.^{82,88,89}

RHEUMATOID PNEUMOCONIOSIS

Rheumatoid pneumoconiosis (Caplan syndrome) was originally described as a variant of PMF in coal workers on the basis of its distinctive radiologic features. Active arthritis or circulating rheumatoid factor were commonly associated with rheumatoid pneumoconiosis.¹ At present, most evidence suggests that the presence of rheumatoid arthritis, a predisposition to rheumatoid disease, or both is a host factor that modifies the response of an individual to coal mine dust exposure. Conversely, dust exposure does not appear to be a risk factor for rheumatoid arthritis.¹ CWP does not appear to have an association with other connective tissue disorders.

ROLE OF SILICA

Although it is recognized that silica does not play a primary role in the causation of CWP, coal miners, especially those mining anthracite, may develop the lesions of silicosis. When present, silicosis is usually associated with CWP.² Although combined exposure to silica and coal dust may produce less silicosis than would a similar pure exposure to silica, silica exposure is nevertheless thought to contribute to the risk of developing PMF.⁴

AIRFLOW OBSTRUCTION AND CHRONIC BRONCHITIS

The association between coal mining and obstructive lung disease has now been confirmed by several longitudinal studies that show that airflow can be limited from coal dust exposure independently from CWP and that the effect becomes comparable with that of smoking at exposure levels at which there is a risk for CWP.^{4,55,90}

Mucus hypersecretion (chronic bronchitis) is common in coal workers but does not appear to play a direct role in their development of COPD. Mucus hypersecretion will generally resolve after withdrawal from dust exposure as it does after smoking cessation. Bronchial hyperresponsiveness appears to predispose coal workers to develop COPD.

TUBERCULOSIS AND CANCER

Mycobacterial infection, either by *M. tuberculosis* (see eFig. 73-7) or nontuberculous mycobacteria, has not been demonstrated to be more common in association with CWP in the absence of silicosis.⁹¹ Most evidence suggests that the occupation of coal mining is not associated with lung cancer; however, two recent studies have reported an association between lung cancer and coal mining.^{91a,91b} An increased risk of stomach cancer has been documented,^{2,4,92} but this was not apparent in a 23-year follow-up study of 8899 coal miners.⁷⁸

CLINICAL FEATURES

Simple CWP is regarded as a disease state without symptoms or physical signs. The diagnosis is based on the radiologic features. The symptoms of cough and sputum reported by most coal miners are likely to be the consequence of dust-induced chronic bronchitis.⁵⁵ Breathlessness on effort is usually caused by associated chronic airflow limitation or by the development of PMF.⁴ Respiratory impairment and disability develop as PMF progresses, although patients with category A PMF (lesions 1 to 5 cm in diameter) may be asymptomatic. Lesions of PMF that impinge on airways may cause abnormal breath sounds. Large or bilateral PMF lesions may be associated with hypoxemia and right heart failure. The presence of new lung lesions with rheumatoid arthritis, subcutaneous rheumatoid nodules, or positive rheumatoid factor raises the possibility of rheumatoid pneumoconiosis. The lung lesions may or may not develop concomitantly with joint disease.

CHEST RADIOGRAPHY

The hallmark of simple CWP on the chest radiograph is the presence of small rounded opacities in the lung parenchyma (eFig. 73-8).^{1,5} (See the discussion of chest radiographs in the "Introduction" to this chapter.) Coal macules are usually associated with small (<1.5 mm) p nodules on the chest radiograph, but the radiograph may show no nodularity with mild to moderate grades of CWP. Large amounts of coal dust in the lungs are found in association with small, rounded p nodules. When the larger q and r nodules are visible radiologically, this usually reflects the

presence of coal nodules and a higher proportion of quartz in the lungs.⁹³

Because the chest radiograph has been shown to be insensitive to the presence of macules and nodules,⁹³ in individual cases, CT may be useful. Small rounded opacities are usually seen first in the upper zones and involve the other zones at a later stage. The nodule profusion is closely related to the lung dust content at autopsy.⁹³ Small irregular opacities also appear in a profusion up to 1/0 in association with increasing age and smoking and, in coal workers, may relate to coexisting fibrosis and emphysema. Small rounded opacities probably never regress, but the presence of emphysema appears to reduce the reading of profusion on the chest radiograph. Some enlargement of hilar nodes is usual, but eggshell calcification is unusual. In a recent report, the presence of small irregular shadows indicating the presence of interstitial fibrosis has been described as a feature in those with exposure to coal dust and the same report disputes the conventional view that nodular opacities in CWP are predominantly in the upper lung zones.⁷³

PMF is diagnosed radiologically when the parenchymal opacities exceed 1 cm in diameter, a cutoff point that is arbitrary in what is obviously a continuous process, as shown by the pathologic demonstration of PMF without associated radiologic features.⁹³ Conversely, approximately one third of cases diagnosed as PMF on the radiograph have been shown, at autopsy, to represent other lesions, including tumors, rheumatoid nodules, or tuberculosis scars.⁹³ PMF lesions are more common in the upper lobes, are situated posteriorly, and are usually well demarcated from the adjacent lung. As PMF becomes more advanced, the lesions are nearly always bilateral (see Figs. 73-6 and 73-7). They may take on bizarre shapes, cavitate, or calcify. As the lesions shrink toward the hilum or to the apex, bullous lesions may be seen in the surrounding lung.

Lesions seen on the chest radiograph in rheumatoid pneumoconiosis are similar to those of PMF but are usually multiple and peripherally located. The lesions, which range in diameter from 0.5 to 5.0 cm, may appear within weeks. These lesions generally appear in the presence of lesser degrees of nodule profusion than are usual for PMF. They may cavitate, contain fluid levels, and show some calcification surrounding the cavity. In some cases, the lesions disappear, often completely, but may be followed at a later date by a fresh crop of lesions. The ILO classification of radiographs provides a special notation for lesions thought to be rheumatoid pneumoconiosis.⁵

LUNG FUNCTION

The controversy regarding the association between simple CWP and abnormal lung function has persisted largely because coal dust has been shown to cause both obstructive lung disease⁹⁴ and pneumoconiosis. In general, it is probably true that simple CWP is a condition with little demonstrable effect on lung function. In part, this may be due to the health selection effect into a dusty job.⁵⁵ Small irregular opacities and PMF have each been shown to be associated with abnormal lung function.^{4,95} Lung function deficits in complicated CWP include reduction in FVC and FEV₁, increased *total lung capacity* (TLC) and residual volume, and decreased DL_{CO} (particularly in the presence of

mixed rounded and irregular opacities). Similar changes have also been noted in nonsmoking coal miners without CWP.⁴ Pulmonary hypertension may develop in proportion to the reduction of the vascular bed associated with advanced PMF.

DIAGNOSIS, COMPLICATIONS, AND MANAGEMENT

A history of occupational exposure to coal and a chest radiograph are the fundamental elements in the diagnosis of CWP. A CT scan of the chest may be used to demonstrate evidence of CWP when the features on the radiograph are inconclusive.

There are no data to suggest that CWP alone carries an increased risk for mycobacterial infection, either tuberculous or nontuberculous, but treatment of latent tuberculosis infection should be considered for coal workers who are thought to have had significant silica dust exposure or who have evidence of silicosis. Other complications include rheumatoid nodules, which are associated more commonly with coal mining than with gold mining exposure, and scleroderma, in which the opposite is true. Most evidence suggests that the occupation of coal mining is not associated with a risk of lung cancer, but some data suggest and some data refute an increased risk of stomach cancer.^{4,78}

The principles of management are those summarized in the “Introduction” to this chapter and elaborated in the section on “Silicosis.” Subjects with radiologic disease of profusion category 1 or greater should be advised to change their occupation to one in which they are no longer exposed to dust because of their risk of developing PMF. Management of other dust-related, smoking-related, or dust- and smoking-related diseases, such as chronic bronchitis and emphysema, is less straightforward. Smoking-cessation counseling should be given on general principles. Although there are no data to show any interaction between smoking and CWP, both coal mining and smoking have the capacity to cause COPD.⁷⁷

ASBESTOS-RELATED FIBROSIS OF THE LUNGS (ASBESTOSIS) AND PLEURA

ASBESTOS MINERALS

History and Uses

Asbestos is an ancient mineral exploited by humans from prehistoric times because of its durability and heat resistance and its fibrous nature, which enabled it to be spun.^{1,96} Commercial use of asbestos grew with mechanization; growth was exponential between the two world wars. Annual production peaked over 5 million tons in 1976 and stabilized at approximately 4 million tons in the early 1980s. Production began to fall in Europe and North America only in the late 1980s, when the ill health effects of exposure became a matter of increasing public concern.¹ In 2010, the world consumption of asbestos, mainly chrysotile, was estimated to have been 2 million tons. By contrast, annual

world production of the nonasbestos mineral silicates is approximately 30 million tons. The use of substitutes has increased proportionately as the use of asbestos has been restricted or banned, although in 2012, only 54 countries had banned or severely restricted the use of asbestos. On the African, Asian, and South American continents, asbestos continues to be in demand as a cheap, durable material for use in water reticulation and in housing projects for their rapidly urbanizing populations, and in many countries, the consumption of asbestos remains high and is increasing.⁹⁷

The word *asbestos* (meaning “unquenchable” in Greek) is used currently as a collective term for naturally occurring mineral silicates of the serpentine and amphibole group. Despite different origins and physical and chemical properties, these silicates have in common a fibrous habit, that is, they form naturally in bundles from which fibers can be easily separated.

As a basis for standard setting, the *Occupational Safety and Health Administration* (OSHA) defines a fiber as a particle more than 5 μm in length with an aspect ratio equal to or greater than 3:1.

Table 73-2 lists some of the mineral silicates found in human lung tissue and gives a general indication of their commercial uses. From the point of view of health effects, the most important are asbestos fibers and man-made mineral fibers. Biologic potency (and disease-producing potential) depends in general on dose delivered to the target organ, fiber dimensions, and durability in the lung tissue. The role of each of these parameters may not be the same for all fibers and all disease entities. Nonfibrous particles greater than 10 μm seldom reach the lung parenchyma, whereas fibers up to 200 μm can be found in the lungs if their diameter is less than 3 μm .²

Sources of Human Exposure

Table 73-2 gives a list of the more common sources for human exposure to asbestos.¹ The discussion that follows deals mainly with exposure to asbestos fibers; the principles, however, apply equally to exposure to other fibers.

In industrialized countries, and increasingly in industrializing countries, human exposure is most likely to be *occupational* and may happen in mining, milling, transporting, manufacturing, and applying or using raw fiber or manufactured products. In World War II, a major source of exposure was in the naval shipbuilding, repair, or refitting industries; in the post–World War II period, major sources of exposure were in the construction and transport industries, although exposures in shipbuilding, repair, or refitting continued to pose risks. Asbestos-containing materials in post–World War II buildings include boards, panels, surfacing, insulation, tile and floor covering, roofing, and caulking. Workers are thus exposed in maintenance operations or demolition of plants and buildings in which asbestos-containing materials have been used. Other sources of human exposure are during the removal of asbestos lagging or insulation from ships or buildings and the disposal of industrial waste, such as the dumps of defunct asbestos plants. In most industrialized countries, these sources of exposure have diminished in response to heightened public awareness and control regulations. However, as recently as 2004, the U.S. Department of Labor estimated that 1.3

million workers remained exposed to asbestos in the workplace, notably in construction and general industry in the United States⁹⁸ and, in a more recent report, ongoing asbestos exposure is also attributed to local and imported, asbestos-containing goods.⁹⁹ Data do suggest that asbestos exposure has decreased, although a recent study from the United States comparing those examined between 1980 and 1992 and those examined between 1993 and 2005 found an unexplained increase in crocidolite fibers in the lungs from 819 subjects with lung cancer, malignant mesothelioma, and asbestosis.¹⁰⁰

Indirect occupational exposure, also called *bystander exposure*, describes the exposure of those whose trades require them to work in the vicinity of others who are working directly with asbestos or asbestos-containing materials. Examples are carpenters and welders who may work in close contact with insulators and ladders who mix asbestos on site, often in closed spaces. Workers were often indirectly exposed in the shipbuilding, repair, and refitting industries and the construction industries.

Domestic exposure happened primarily as a consequence of fiber-laden work clothes being brought home. Domestic exposure still accounts for a small proportion of cases of asbestos-related disease, mainly pleural, and is reported to have accounted for up to 15% of malignant mesothelioma in one U.K. study.¹⁰¹ Given the long incubation period of this tumor (from 20 to 40 years), domestic exposure is likely to be the source of cases presenting well into the 21st century.

Environmental and residential exposure takes place as a consequence of living in the neighborhood of asbestos mines, mills, or plants.¹⁰² This source of exposure was first dramatically brought to medical attention in 1960 in a report of a cluster of 31 cases of malignant mesothelioma among residents and crocidolite asbestos miners of the Northwest Cape, South Africa.¹⁰³ New cases were reported from this area until 1995, and because occupational and environmental exposure continued until the 1970s, cases were expected to continue and to increase up to and beyond 2010.¹⁰⁴ A cohort study comparing the mortality experience of more than 4500 women living in the vicinity of the Quebec chrysotile mines with that of 1.375 million women from 60 reference areas in the province found seven deaths from mesothelioma in women living in the asbestos mining area and none in the reference population.¹⁰² Vermiculite mined from Libby, Montana, and shipped around the country was found to be contaminated with asbestos fibers. Residents of Minneapolis who had lived near waste piles of Libby vermiculite and who had never worked in the vermiculite industry have been found to have a high prevalence of asbestos-related pleural disease, greater if they ever played in or had contact with the waste piles.¹⁰⁵ Similar waste piles associated with the remote processing of Libby vermiculite are estimated to exist in 250 sites across the United States. A community-based study in Libby found that localized pleural abnormalities were associated with restrictive pulmonary function.¹⁰⁶ Environmental exposures from nonindustrial sources have been documented among residents of rural areas in Eastern Europe where the soil is contaminated with various fibers.¹⁰⁷ In addition, there have been epidemics of asbestos-related pleural disease, nonmalignant and malignant, among residents of

Table 73-2 Mineral Silicates That Have Been Found in Human Lung Tissue*

Mineral: Group and Form	Location of Major Deposits, Commercial or Other	Main Commercial Uses and/or Other Sources of Human Exposure
ASBESTOS MINERALS		
Serpentine		
Chrysotile [†] (white asbestos)	Canada (Quebec, British Columbia, Yukon, Newfoundland [‡]), Russia, China (Szechwan), Brazil, Mediterranean countries (Cyprus, Corsica, Greece, Italy), southern Africa (South Africa, Zimbabwe, Swaziland)	Brake lining, shipbuilding and repair, polishing of precious stones, stone cutting, whetstone cutting, foundry operations (mainly for insulation) Asbestos cement products (pipes, gutters, tiles, roofing); insulation, fireproofing, reinforced plastics (fan blades, electric switchgear); textiles; friction materials; paper products; filters, spray-on products
Amphibole		
Crocidolite (blue asbestos)	South Africa (Northwest Cape [‡]), western Australia [‡]	Used in combination, mostly in cement but also in some of the products listed above
Amosite (brown asbestos)	South Africa (Northern Province, former Transvaal)	
Anthophyllite	Finland [‡]	Filler in rubber and plastics
Tremolite	Contaminates ore in certain talc, iron, and vermiculite mines (e.g., Libby, MT); also found in some agricultural soils	May or may not be removed in processing; has rural domestic uses (e.g., stucco)
Cummington-grunerite	Contaminates ore in certain iron mines (often not fibrous)	No commercial use
NONASBESTOS MINERAL SILICATES		
Clay minerals (usually fine-grained, powder-like) such as kaolin and montmorillonite (bentonite)	40 countries, including China, United States (Georgia, North Carolina), United Kingdom (Cornwall), Germany, Egypt, Japan	Functional filler in paper, plastic, bricks and cement, rubber, paint, etc.; fire clays, refractories, ceramics, lubricants
Attapulgite and sepiolite	United States (Georgia, Florida), Spain, Australia, South Africa	Oil absorbants; pesticide carriers; pet litter
Talcs (usually platelike but can roll into scrolls)	United States (Vermont, Montana, New York, California), Italy, Spain, Norway, China, Japan, Korea, Canada	Ceramics; paper making; cosmetics; pharmaceuticals; animal feed; fertilizer; anticaking; paints; varnishes; plastic reinforcer
Micas (Usually Flaky) Muscovite	United States (North Carolina, Georgia, and other states), France, Spain, China, India, Italy	Filler in plastics, drill sites, special paints; refractories; semiconductors; insulation; anticorrosion materials; welding rods
Vermiculite (expands when heated)	South Africa, United States (Montana, Virginia), Australia, Kenya	Absorbents (horticulture); plasters; boards; insulation; fire resistance
Wollastonite (exists as needles or fibers in limestones)	United States (California, New York), Japan, former USSR, Finland, Mexico, Australia	Filler/flux in ceramic industry; used in latex and oil-based paint; in welding fluxes; asbestos substitute in hardboard, insulation, and brake linings
Zeolite (fibrous), e.g., Erionite [§]	Turkey (Cappadocia and Anatolia regions) [§] ; noncommercial deposits	Houses constructed in erionite rock; soil-containing fibers mixed with tremolite; sepiolite used in stucco and plaster
Other (mainly nonfibrous)	Worldwide (in filling of lava cavities); mined in 16 countries, including several in Europe, the United States, and Japan	Pollutant and radioactive waste control; also used in catalysts, adsorbents, conditioners
MAN-MADE MINERAL FIBERS		
Glass wool and filament, rock wool, slagwool, ceramic fiber	Production in factories around the world	Many uses previously reserved for asbestos: glass filament used in mats, lamination, yarns; glass-rock and slagwool used as insulation in buildings and in car and naval construction; ceramic fiber used in reinforced cloth, disks, brakes, gaskets, board, and paper; high-performance ceramic fiber used in jet engines, spacecraft

*The list is not exhaustive, and the reader should consult other sources^{1,2,170,171} for further information. Asbestos minerals invariably exhibit the fibrous habit; nonasbestos mineral silicates also may do so. Most silicate deposits are mineralogically heterogeneous, as are most of the commercial forms of the minerals.¹⁷⁰

[†]Accounts for more than 90% of the world's commercial production; other fibers still used in combination with chrysotile.

[‡]Mining no longer in operation.

[§]One of three epidemics of mesothelioma in Turkish villages implicated erionite; in the other two, tremolite and/or chrysotile were implicated.¹⁰⁷ As of 2012, 54 countries have prohibited the use of asbestos or severely restricted its use, but in all countries, exemptions are allowed for certain uses. A prohibition decree was adopted to be enforced in the European Community in 2005.

Turkish villages whose homes were constructed in erionite tuff rock or who used erionite and tremolite in stucco and plaster¹⁰⁷ and in Da-yao, southwestern China, where crocidolite is present in the soil.^{102,108} A major concern since the 1980s has been the potential risk of exposure to occupants of public (including schools), commercial, and residential buildings constructed during the post-World War II period, when asbestos-containing materials were widely used in construction. A health review mandated by the U.S. Congress concluded that exposure in buildings was less by an order of magnitude than that encountered in the workplace except for custodians and others responsible for building maintenance.¹⁰⁹ The report also provided estimates of lifetime cancer risk (see “[Asbestosis, Asbestos Exposure, Lung Cancer, and Mesothelioma](#)” later).

Fate of Inhaled Fibers

Accumulation of fibers in the lung is the outcome of exposure, deposition, clearance, and retention, all processes that depend on fiber dimensions and the level, intensity, and profile of exposure.¹¹⁰⁻¹¹² Clearance of fibers from the lung is greater for short and for chrysotile fibers than for long and amphibole fibers.¹¹³ Retention of fibers is inhomogeneous, with more fibers being found in the lung regions with shorter pathways and greater accumulations of longer fibers with asbestosis than in lungs in which only airway lesions have developed.¹¹³ Fibers equal to or less than 3 μm are phagocytosed by activated macrophages and then translocated to lymphatic channels. Longer fibers are incompletely phagocytosed, often by more than one macrophage, and become the core of what were originally called *asbestos bodies* because of their association with asbestos exposure. Although most coated fibers in human lungs have been shown to contain asbestos (usually amphibole) when subjected to radiographic diffraction analysis,^{2,96} the term *ferruginous bodies* has been suggested to underline the fact that other mineral fibers may undergo coating in human lungs. (For a discussion of the translocation of fibers to the pleural space, see Chapters 79 and 82.)

In the lungs of exposed individuals, the number of uncoated, or bare, fibers (visible only on electron microscopy) exceeds the number of coated fibers (*asbestos* or *ferruginous* bodies), visible by light microscopy, by 5- to 10,000-fold.¹¹⁵ For many years, the coated asbestos fiber, *asbestos body*, has been considered the hallmark of exposure, past or current, no doubt because of its distinctive structure and because it was readily visible under the light microscope. The presence of more than one coated fiber has been cited (and challenged) as a necessary criterion for the pathologic diagnosis of asbestosis even in a subject with an appropriate exposure history.¹¹⁵ Asbestos bodies may be found in sputum or in BAL fluid when lung tissue levels are high. They are also more commonly found when exposure has been recent and to amphibole rather than chrysotile fibers.^{2,116,117} BAL fluid may also show characteristic cellular, biochemical, and mineralogic features in workers exposed to asbestos and especially in those with asbestosis.¹¹⁸

Exposure versus Dose-Response Relationships

Epidemiologic studies have consistently demonstrated exposure-response relationships for asbestos-related paren-

chymal lung fibrosis.¹¹⁹ There are differences in the exposure-response relationships between industrial sectors, which probably reflect the fiber size (smaller fibers causing more lung disease) and the nature of the fibers, their retention, and their biopersistence in lung tissue (amphiboles causing more disease than chrysotile). For asbestos-related pleural disease, exposure-response relationships can also usually be demonstrated, but the residence time of the dust in the lungs is more important than the cumulative exposure.^{111,114} Mineralogic analysis has also shown that the degree of fibrosis correlates with fiber concentration, both in chrysotile- and in amosite-exposed workers. The toxicity of mineral fibers is determined by their physical and aerodynamic properties, which determine deposition and retention. Also relevant in fibrogenesis and probably in carcinogenesis is the solubility of the fibers (which determines their survival in lung tissue), their surface properties and electrical charge (which may affect their toxicity for cell membranes and the formation of free radicals), and the length-to-width aspect ratio (which may affect cellular toxicity).^{2,35}

ASBESTOSIS (PULMONARY PARENCHYMAL FIBROSIS)

Pathology and Pathogenesis

Asbestosis tends to be prominent in the lower lobes and subpleural areas. The lesions of mild asbestosis are found at scattered sites and usually consist of foci of peribronchiolar fibrosis¹²⁰ with local chronic interstitial inflammation, accumulation of macrophages in the air spaces, and proliferation of type II pneumocytes. Second- and third-order bronchioles and alveolar ducts tend to be involved as the disease progresses and the fibrosis spreads to involve the alveolar interstitium (Fig. 73-8A). When disease is advanced, the lungs are small, streaks of fibrosis outline lobar and interlobar septa, and the visceral pleura is invariably thickened. Honeycombing may be prominent subpleurally and in the lower lobes. Unlike in silicosis, the tracheobronchial lymph nodes do not show characteristic changes and progressive massive fibrosis is unusual.¹¹⁵ Advanced asbestos-related fibrosis is distinguishable from advanced fibrosis due to any other cause only by the presence of asbestos bodies or uncoated asbestos fibers (Fig. 73-8B).²

In general, the grade of pulmonary fibrosis relates to the fiber burden carried by the lungs.² On the basis of animal and human data,^{35,121,122} asbestosis is thought to commence with an alveolitis that may resolve if the fiber burden is low and the fibers are cleared. If the fiber load is low but retained, a nonprogressive distal airway lesion, mineral dust-induced peripheral airway disease, may develop.^{35,113,120-122} If the dust load retained is high and phagocytosis of fibers by alveolar and interstitial macrophages is incomplete, fibronectin is released together with other proinflammatory and cytotoxic agents such as free oxygen radicals. These interact with and recruit fibroblasts to the site of the injury, where they proliferate and lay down collagen. If sustained, this leads to irreversible damage, loss of alveolar spaces, and the development of chronic interstitial lung fibrosis, asbestosis.¹¹³

Figure 73-8 Pathologic features of asbestosis: examples from South African asbestos workers. **A**, Asbestos bodies (arrow) with commencing fibrosis. The architecture of the surrounding lung parenchyma is preserved. **B**, Diffuse interstitial fibrosis with destruction of the lung architecture and honeycombing; asbestos bodies are seen in the air spaces and interstitial tissue (arrow). (Courtesy National Institute for Occupational Health, South Africa.)

Epidemiology and Natural History

Clinical asbestosis is becoming less frequent and less severe as exposure levels in workplaces around the world are increasingly meeting currently recommended control levels.^{111,123} However, in the United States, although mortality rates for the other pneumoconioses (CWP and silicosis) are declining, the rate for asbestosis increased possibly by as much as 10-fold between 1968 and 1999^{25,80} and is not expected to decrease before 2024.¹²⁴ A similar trend was apparent in Australia,¹²⁵ while in the United Kingdom and Canada, rates of certification of death or disability from asbestosis were reported to be falling.^{126,127} However, a recent report from the United Kingdom shows that, while other pneumoconioses were becoming less common, the incidence of asbestosis in the United Kingdom continued to rise until 2005 and decreased only slightly since that time.¹²⁸ With low-level exposure to asbestos, the interval between exposure and disease increases.¹¹¹ The pattern of exposure also determines the nature of the disease. In occupations in which exposure is intermittent but of high intensity, the ratio of pleural-to-parenchymal radiologic abnormalities may exceed 20, whereas in occupations in which workers are more consistently exposed, the ratio of pleural-to-parenchymal abnormalities is closer to 2 : 1.^{111,129} Exposure at a young age is an independent determinant of both attack and progression rates of parenchymal and pleural radiologic abnormalities, suggesting that residence time of dust in the lung is important in their pathogenesis.^{111,129,130} Other determinants of progression are level and duration of exposure, cumulative exposure, and fiber type; asbestosis is more frequent after exposure to the amphiboles, crocidolite and amosite, or mixtures of amphibole and chrysotile than to chrysotile alone.¹¹¹ Once established, radiologic asbestosis will usually progress.¹²⁹ Radiologic asbestosis may appear and progress long after exposure ceases; in a study of chrysotile miners and millers in Quebec, appearance and progression rates of 31% and 9%, respectively, were recorded for pleuroparenchymal disease over an average follow-up period of 17 years after exposure.^{111,129} Progression in the absence of further exposure relates to cumulative exposure up to the time of leaving work.^{111,130} Genetic features appear to play a role in determining the development and extent of asbestos-induced lung fibrosis.^{111,131,132}

Smoking deserves comment because of its role as a universal risk factor for respiratory disease, both malignant and nonmalignant. There is some evidence that the milder grades of radiologic small irregular opacities on the ILO classification may be caused by smoking. Pathologic studies do not show evidence of an association between asbestosis grade and smoking,¹³³ although there is evidence to suggest that smoking enhances the retention of fibers in the lungs.^{2,133}

Clinical Features

Asbestosis is characteristically associated with dyspnea. Dyspnea often precedes other evidence of disease and, therefore, may be underrated by the physician because of its subjective nature. However, the consistency of its relationship to exposure levels¹¹¹ suggests that it is related to early parenchymal asbestosis. Persistent dry cough is reported commonly, almost as frequently as dyspnea in some series,^{114,134} and has been attributed to the stimulation of lung receptors. Chest tightness or pain, or both, are not uncommon and may be caused by acute asbestos-associated pleural reactions.

Basal crackles, an early and distinctive feature of asbestosis, are fine, crisp, persistent sounds, often heard first over axillary and basal regions and then more generally as the disease advances.⁹⁸ Other sounds, including coarse crackles and rhonchi, reflect airway disease that may be related to cigarette smoking or to dust in the occupational environment.¹³⁵ Clubbing of the fingers and, occasionally, the toes develops in some subjects. Late manifestations include respiratory and circulatory failure, and these, with cancer, are common causes of death.

Radiographic Features

The posteroanterior chest radiograph remains a key tool in the initial clinical diagnosis of asbestosis and in the health surveillance of exposed workers. The ILO classification⁵ uses the term “small irregular opacities” to describe the irregular linear shadows that develop in the lung parenchyma and obscure the normal bronchovascular arborization pattern seen in disease-free lungs. The parenchymal opacities are usually seen first in the lower lateral zones (eFig. 73-9). As their profusion increases, the borders of the heart may be obscured (eFig. 73-10). Small rounded

opacities are unusual when the exposure has been primarily to fibers but are more likely to be seen in workers who also have had silica exposure (e.g., asbestos cement workers).^{1,19}

Early fibrotic changes are better visualized by HRCT with supplementary prone images (eFig. 73-11),¹¹⁸ particularly for subpleural parenchymal changes that may be obscured by overlying pleural fibrosis on the chest radiograph (eFig. 73-12).¹³⁶ Visceral pleural thickening of the interlobar fissures is common.¹¹⁴ Changes in the parietal pleura (see later) are also common, and the presence of pleural plaques (particularly if they are bilateral) (see eFig. 73-12) or of pleural thickening provides additional evidence that the parenchymal disease is asbestos related. Hilar node enlargement is not a feature of asbestosis, and PMF lesions, including rheumatoid pneumoconiosis, are less common than in workers exposed to coal or silica. The radiologic features of well-developed disease seldom present a diagnostic problem, whereas the detection of less advanced disease may require the use of ILO films and HRCT. The CT scan is also useful in characterizing localized pleuropulmonary lesions, including rounded atelectasis (eFig. 73-13A-D, Video 73-4), which must be distinguished from lung cancer because it usually presents as a solid localized lesion (Fig. 73-9). HRCT can also identify coexisting lung disease such as emphysema and distinguish subpleural fat from pleural thickening and plaques (eFig. 73-14).

Lung Function

Established asbestosis is often, but certainly not always, associated with a restrictive lung function profile; reduced FVC, *total lung capacity* (TLC) and DL_{CO} . In studies of exposed populations, a substantial proportion of subjects (up to half in some series)¹²⁹ exhibit a mixed or obstructive function profile in keeping with the parallel development of airway

and parenchymal effects of working in dusty occupations contaminated by mineral dusts.⁷⁵ When repeated lung function tests are used to assess progression of disease, simple volume measurements such as FVC appear to be the most useful.^{96,129,137}

Diagnosis and Complications

Criteria for diagnosis depend on the purpose for which a diagnosis is required. Clinical diagnosis depends on establishing the presence, extent, and nature of pulmonary fibrosis and whether the exposure has been of a duration and intensity sufficient to put the individual at risk for developing asbestosis. The fewer the features, the less certain the diagnosis is; the more trivial the exposure, the less likely it is to be causal. When radiologic or lung function changes are marginal, other imaging, including CT or HRCT, may be helpful. In the absence of what appears to be an adequate exposure history, it may be appropriate to perform a biopsy of the lung to establish the nature of the disease and the presence and burden of asbestos in the lung. Sputum analysis may be useful for identifying asbestos bodies as an indication of lung dust burden but is far less sensitive than BAL.^{98,118,138} Diagnosis of asbestosis for the purpose of legal attribution calls for greater certainty and the use of criteria that vary according to the legal administrative system involved. Most published criteria consider histopathology as the best means of establishing the diagnosis.¹¹³ In its absence, the following criteria are proposed: (1) a reliable history of asbestos exposure; (2) an appropriate lag time between exposure and detection; (3) evidence of lung fibrosis on the chest radiograph or HRCT scan; (4) a restrictive pattern of lung function; (5) bilateral fixed inspiratory crackles; and (6) clubbing of the fingers or toes, or both. Of these, history of exposure and radiographic evidence are considered essential and the others confirmatory.¹¹³

Figure 73-9 Asbestos-related pulmonary parenchymal and pleural disease (bilateral pleural fibrosis and atypical rounded atelectasis) in a 50-year-old man. The patient had worked as an electrician since the age of 17 years, first in construction for 10 years (with known exposure to asbestos), then briefly on naval ships during World War II, and in a chemical plant (with known exposure to talc) for the past 20 years. His exercise tolerance was excellent and his only complaint was a dry cough. Chest radiographic abnormalities had been noted 4 years previously. **A**, Posteroanterior chest radiograph shows bilateral diaphragmatic plaques, extensive bilateral pleural thickening (arrowheads), and a circumscribed lesion in the right mid-lung zone that had increased in size over the past year (arrow). **B**, On CT, the pleural plaques were shown to be much more extensive than appeared from the chest radiograph. Many plaques (arrows) were calcified. In addition, HRCT revealed bands of subpleural fibrosis related to the pleural plaques or thickening, or both. Lung volumes and carbon monoxide diffusing capacity were greater than 100% and 98% of predicted values, respectively. Because the circumscribed lesion (arrow in **C**) had enlarged over the past year, it was removed surgically. The lesion, which was nonmalignant, consisted of pleural, subpleural, and interstitial fibrosis. Analysis of lung digest revealed the following: 36 asbestos bodies/mg of dry lung tissue and 7570 fibers/mg of dry lung tissue, more than half of which were asbestos fibers and less than 1% of which were talc. These findings implicated his earlier, rather than his more recent, occupational exposures as the cause of his pleural disease. (Dr. J. Kosiuk, Department of Radiology, Royal Victoria Hospital, Montreal, carried out the radiographic studies; Dr. A. Dufresne, School of Occupational Health, McGill University, carried out the lung dust analyses.)

The individual with asbestosis is at increased risk for cancer of the lung^{139,140} and, by virtue of asbestos exposure, is also at risk for mesothelioma. Working in a dusty occupation also puts the worker at risk for developing COPD.⁷⁵ Tuberculosis and rheumatoid pneumoconiosis are uncommon complications of asbestosis.

Asbestosis, Asbestos Exposure, Lung Cancer, and Mesothelioma (see Chapters 52 and 82)

In 1977 the *International Agency for Research on Cancer* (IARC) classified asbestos as a human carcinogen, the target sites being lung, larynx, and pleura.¹³⁹ Since that date, a considerable body of evidence has accumulated in support of this view that lung cancer is associated with asbestos exposure with or without asbestosis,¹⁴¹⁻¹⁴³ although there are still dissenting views.² The lung cancer risk is enhanced by cigarette smoking, and the independent and joint impacts of smoking, asbestos exposure, and asbestosis are discussed in a recent paper in which smoking and asbestos exposure are described as having an additive effect, whereas smoking and asbestosis have a “supra-additive” effect on the risk of dying from lung cancer.¹⁴⁴ This report shows a substantial fall in the risk for lung cancer when asbestos-exposed insulator workers stop smoking; the risk is halved at 10 years after stopping smoking and is reduced to that of a nonsmoker after 30 years.¹⁴⁴ Other factors influencing the risk of lung cancer in exposed workforces include industry (risk greater in the textile vs. the asbestos cement industry), fiber type (risk greater when exposure is to amphibole, crocidolite, amosite or tremolite, or mixed amphibole-chrysotile than when it is only to chrysotile), and fiber dimensions (longer fibers are more carcinogenic than shorter fibers).^{113,145}

The introduction of workplace dust exposure controls has resulted in an increase in the emergence of cancer as opposed to asbestosis as an important cause of death in asbestos-exposed individuals. This is explained by the fact that the asbestos-dust burden is much lower in cases of lung cancer than it is in cases of asbestosis. For instance, in chrysotile miners in Quebec, the fiber concentrations in those dying of asbestosis versus those dying of lung cancer versus those nonexposed were 30 versus 13 versus 2 million chrysotile fibers per gram dry lung tissue; for those engaged in trades with asbestos exposure in the Pacific Northwest, where amosite was the dominant fiber, the equivalent figures were 10.0 versus 1.0 versus 0.7 million fibers per gram of dry lung tissue.¹³³ All histologic cell types of lung cancer have been shown to be associated with asbestos exposure, which further supports the direct role of asbestos, independently from asbestosis, as a carcinogen.¹⁴⁶

Of great concern to the public has been the risk of cancer from attending school or working in a building constructed with asbestos-containing materials. The lifetime risk for premature cancer death from exposure at school from age 5 to 18 years has been estimated at 6 per million exposed and, for working in an office building with asbestos-containing material, at 4 per million exposed; these risks are compared with a risk of 2000 per million for 20 years employed in a workplace conforming to 0.1 fiber/mL, the current permissible exposure limit proposed by OSHA.¹⁰⁹ Malignant mesothelioma has been reported in school

teachers; population studies have failed to show an increase in the incidence of mesothelioma in relation to the use of asbestos in buildings.¹⁰⁹

PLEURAL PLAQUES

Pathology and Pathogenesis

Pleural plaques are distinctive, smooth, white, raised lesions with irregular borders usually found on the parietal and rarely on the visceral pleura (eFig. 73-15). They may vary from small to extensive and are usually nonadherent to the lung. Common sites are the posterolateral midzones, where they may follow the rib contour, and on the diaphragm. They are less commonly found on the pleura adjacent to the mediastinum and pericardium and, rarely, in the apices and costophrenic sulci.¹¹⁴ On microscopic section, pleural plaques consist of avascular, acellular, laminated collagen fibers arranged parallel to the surface or in whorls, with hyaline changes and occasional fibroblasts. Macroscopic calcification is common, and microscopic calcification is extremely common, especially in the parietal lesions. The lesions are usually covered by mesothelium. Fine asbestos fibers are seen on electron microscopy.¹¹⁴ The lungs of patients from the general population who have plaques have been shown to contain a 50- to 250-fold excess of long, thin, mainly amphibole fibers.² In asbestos miners and millers in Quebec and in those engaged in the Pacific Northwest trades that involve exposure to asbestos, the lung burden is similar to that seen in association with lung cancer (see earlier).¹¹⁴ Pleural plaques are thought to develop after the movement of fibers into the pleural space (see also Chapter 82). Once the fibers are within the pleural space, macrophage and cellular interactions may determine fiber localization and plaque formation. In the absence of macrophages, the pleural reaction tends to be disorganized and diffuse.¹⁴⁷ The parietal location may be due to the fact that for fibers, as for macrophages, the only exit from the pleural space is via stomata that communicate directly with the parietal pleural lymphatic channels. Pleural fibrosis and pleural plaques may have the same pathogenesis.²

Clinical Features

Pleural plaques, in the absence of parenchymal disease, often do not cause signs and symptoms and are usually detected as an incidental finding on a routine chest radiograph. Their visualization depends on their thickness and the orientation of the x-ray beam. Only a modest proportion of those seen at autopsy are detected on posteroanterior chest radiographs (see eFigs. 73-9, 73-10, 73-12A); oblique views increase the yield. CT and HRCT scans can identify plaques at an earlier, less well-developed stage (eFig. 73-13B-E) and can differentiate plaques from extrapleural fat pads. In the past, pleural plaques have been labeled as “visiting cards” for asbestos exposure, implying that they had no impact on lung function at rest or on effort. In fact, in epidemiologic studies, lung volumes (mainly vital capacity and FVC) of those with pleural plaques are on average modestly but consistently reduced.¹⁰⁶ The DL_{CO} is generally normal.^{114,129,137} Increasingly, too, it is recognized that in some individuals, pleural plaques may be associated with

disability.¹⁴⁸ The underlying mechanism may be inhibition of inspiratory capacity during exercise, resulting in an increase in the work of breathing.

Epidemiology

Pleural plaques continue to be the most frequent and often the only manifestation of asbestos exposure,^{114,127,149} and asbestos exposure is the most common cause of pleural plaques. Bilateral pleural plaques are more likely to be associated with asbestos exposure than unilateral plaques, for which other causes should be considered.⁹⁸ Age and residence time of dust in the lungs are determinants of these distinctive pleural lesions¹¹⁴; smoking is considered to be a determinant by some¹ but not in general.¹¹⁴ Domestic and residential exposures have been implicated in the production of pleural plaques (see earlier, the discussion of human exposure in the section on “Asbestos Minerals”), with remarkably high rates for pleural calcification ($\leq 30\%$) being described in some rural communities in the eastern Mediterranean countries of Corsica, Greece, Cyprus, and Turkey.¹⁰⁷ Environmental (nonoccupational) exposure to the asbestos-contaminated vermiculite from Libby, Montana, has also been reported in at least one of the several U.S. sites where this material has been processed.¹⁰⁵ Of greater concern to the patient and the clinician is the prognostic significance of plaques. In one study, they were associated with alveolitis, as reflected in bronchoalveolar cell counts¹⁴⁷ and, by implication, with an increased likelihood of developing parenchymal disease. The results of a Swedish cohort mortality study involving 1596 men were interpreted as showing that pleural plaques on the chest radiograph indicated significant exposure to asbestos, as well as an increased risk of mesothelioma and possibly also for lung cancer.¹⁵⁰ This risk raises the question of screening chest radiographs in those with pleural plaques, a topic that remains controversial in the absence of clear evidence of benefit.^{98,150}

PLEURAL FIBROSIS AND VISCEROPARIETAL REACTIONS

Pathology

Like pleural plaques, pleural fibrosis and visceroparietal pleural reactions may be localized or diffuse and may vary in thickness from a milky discoloration of the lung surface to a thick, white peel encasing much of one or both lungs. The interlobar fissures are commonly involved. Visceral pleural disease may be severe even in the presence of minimal parenchymal reaction.^{114,115} Occasionally, a localized pleural reaction may fold on itself and the surfaces adhere, trapping the underlying lung and leading to a well-defined pleuroparenchymal lesion or pseudotumor, also called *rounded atelectasis*¹¹⁴ (see Fig. 73-9, eFig. 73-13). Asbestos bodies and fibers are usually found in the visceral pleura, the underlying parenchyma, or both,¹¹⁴ and the lung dust burden usually reflects the occupational exposure; however, fiber counts are considerably less than those seen in asbestosis.

Epidemiology

Like pleural plaques, pleural fibrosis and visceroparietal reactions may be found in the absence of radiologic

parenchymal fibrosis and are increasing in frequency.¹¹⁴ The exposures implicated (see Table 73-2) are often short, heavy, remote, and related to amphiboles. Latency is usually long, 34 years in a recent report,¹⁵¹ reflected in the fact that these reactions relate to time since first exposure (a proxy for residence time of dust in the lung) and not to cumulative exposure dose.¹¹⁴ Pleural fibrosis has been reported in association with environmental exposures from mining operations (see previous discussion under “Sources of Human Exposure”) in Finland and South Africa and from nonmining (agricultural) operations in Bulgaria, Czech Republic, Slovakia, Poland, Greece, and Turkey. Epidemiologic studies are also consistent in showing that the presence of pleural fibrosis is associated with reduction in lung function, after any associated parenchymal fibrosis has been taken into account.^{114,129,137}

Diagnosis

Pleural fibrosis is less specific for asbestos exposure than are pleural plaques, and other causes need to be considered in the differential diagnosis. The diagnosis of asbestos-related pleural thickening is usually based initially on the chest radiograph. Clinical presentation, like that of pleural plaques, is often as an incidental abnormality detected on a routine chest radiograph. After careful inquiry, a remote history of exposure, often quite brief but usually heavy, can be obtained from the subject. Rounded atelectasis may present as a radiologic abnormality in an asymptomatic subject, usually with a clear history of exposure. Conversely, some subjects present with breathlessness¹¹⁴ or chest pain, or both, with or without a history of acute episodes, attributed to benign pleural effusions (see later). Pleural fibrosis restricts the movement of the lungs; in the absence of associated parenchymal disease, clinical signs may be minimal, even though functional impairment is detectable. Impairment may be modest even in the presence of severe pleural disease.^{114,129,152} In one study, any pleural abnormality was associated with an average deficit of 0.22 L and 0.40 L for FEV₁ and FVC, respectively,¹⁴⁸ but pleural fibrosis occasionally becomes severe enough to precipitate respiratory and cardiac failure and to require pleurectomy.^{114,153}

The radiologic and CT features of pleural fibrosis are discussed under “Pleural Plaques.” Given a history of exposure, obliteration of the costophrenic angle is likely to represent the residuum of asbestos pleural effusion.¹¹⁴ In rounded atelectasis, the CT scan is particularly useful in delineating the relationship of the rounded lesion to other pleural changes.¹³⁶ Nevertheless, the differential diagnosis of rounded atelectasis includes lung cancer and, in some cases, the diagnosis can be established only by surgery.

BENIGN ASBESTOS-RELATED PLEURAL EFFUSIONS

Benign asbestos-related pleural effusions may arise without evidence of prior pleural involvement from asbestos exposure or may mark an increase in the extent or severity of an already present pleural reaction. The term “benign” does not imply a lack of clinical significance but rather that the effusion is not associated with mesothelioma.¹¹⁴ Benign asbestos-related pleural effusions usually appear within 15

years of the first exposure, often after exposure has ceased,¹¹⁴ with a median of 38 years after first exposure to asbestos.¹⁵¹ They are more common in persons in their 20s and 30s and may be the most common manifestation of asbestos pleural disease in that age group. The episodes are usually transient and may be silent but may be associated with chest tightness and, occasionally, pleural pain, fever, and dyspnea.¹¹⁴ The effusion is usually small, exudative, and bloodstained² and contains leukocytes. Asbestos bodies are rarely found in the fluid, but they may be seen in the underlying parenchyma on biopsy.¹⁵⁴ The sedimentation rate is often raised.¹⁵⁴ Diagnosis is by exclusion, and suggested criteria include (1) an exposure history, (2) the absence of other causes, and (3) absence of tumor on a 3-year follow-up.¹¹³ Because cytologic examination of the pleural fluid is rarely conclusive, a thoracoscopic biopsy is usually required to exclude other causes; to establish the presence of fibers in the pleural fluid (rarely demonstrable), pleura (sometimes demonstrable), or the underlying lung parenchyma (not infrequently demonstrable); and to rule out malignancy, in particular malignant pleural mesothelioma. The usual pathologic findings in benign asbestos-related pleural effusion are those of chronic fibrous pleurisy with minimal cellularity.

The prognosis of benign asbestos-related pleural effusions is generally good; most clear spontaneously, whether it be the first episode or a recurrence. They may recur on the opposite side. Although pleural effusion is a common form of presentation for mesothelioma, there is no evidence that a benign effusion signals a future pleural malignancy. It appears rather to represent a stage in the evolution of asbestos-related pleural fibrosis and also carries a risk of developing parenchymal fibrosis (asbestosis).¹¹¹ The pathogenesis is unknown.² Both inflammatory effects by fibers in the pleura and a direct cytotoxic effect on the surface mesothelial layer have been invoked.¹¹⁴

MANAGEMENT, PREVENTION, AND HEALTH MONITORING

The principles guiding clinical management of all asbestos-related lung and pleural conditions are no different from those guiding management when there is no history of asbestos exposure. However, it is important to make the appropriate notification of a case of asbestos-related disease. Notification, together with any procedure related to compensation, depends on the local jurisdiction. Employment advice should be guided by knowledge of the impact of further exposure on the natural history of the disease processes^{114,115,129} and by the risks for developing additional asbestos-related disease. It is important to emphasize that, even in the absence of any further exposure, all nonmalignant asbestos-related diseases may progress due to the dust load already in the lungs.

No active treatment measures have been shown to influence the course of asbestosis. Patients with end-stage asbestosis have been the recipients of lung and heart-lung transplants, but technical difficulties may arise because of the associated pleural disease.

For the nonmalignant asbestos-related pleural disorders, the evidence is reasonably clear that those with pleural fibrosis are at greater risk for parenchymal fibrosis in the

future.¹¹¹ The presence of pleural fibrosis or pleural plaques is associated with increased risk for malignant pleural mesothelioma and lung cancer.¹⁵⁰ A document from the American College of Chest Physicians highlights areas in which there is and is not consensus regarding the health effects of asbestos exposure.¹⁵⁵

As a public health measure, an international ban on asbestos has been advocated for its control.¹⁵⁶ However, issues associated with an international ban, imposed by the industrialized world, include the lack of inexpensive alternatives for asbestos, especially important in the industrializing world, which currently accounts for much of the asbestos use, and the lack of studies comparable with those conducted on asbestos to examine the safety and effectiveness of substitutes, including man-made fibers.¹⁵⁷ Concern certainly still exists about the potential ill health effects of the man-made substitutes,^{157,158} and even though most data do not suggest that those exposed occupationally have an increased risk of lung cancer or mesothelioma,¹⁵⁹⁻¹⁶¹ recent studies report that exposure to mineral wool¹⁶² and refractory ceramic fibers^{162a} enhanced the risk of mesothelioma in asbestos-exposed workers.

The possible role of smoking in the initiation and progression of fibrotic parenchymal disease and its established role in multiplying the risk of lung cancer are strong indications for smoking-cessation advice to be given to the individual and for instituting smoking-cessation programs for workers in workplaces contaminated by asbestos dust. Quitting tobacco smoking should benefit the asbestos-exposed individual even more than the nonexposed individual because of the interaction of these two agents.¹⁶³

The mesothelioma risk may be expected to decline with time. Although in Europe and Australia, it had been estimated that rates would decline only by the second decade of the 21st century,^{164,165} a 2003 report from a British naval dockyard indicates that rates had already peaked in 1991 and have since fallen.¹⁶⁶ Similar trends have been observed in Sweden, where the rate in men peaked in 1995 and has subsequently fallen,¹⁶⁷ and in the Netherlands.¹⁶⁸ This improvement is attributed, at least in part, to the introduction of asbestos safety guidelines in the 1970s in the countries concerned.

NONASBESTOS MINERAL SILICATES AND LUNG DISEASE

Exposure to some of the nonasbestos mineral silicates listed in Table 73-2 has been associated with lung disease. Silicate dust particles are found in the lungs of most urban dwellers¹⁶⁹ and, in general, they appear to have low biologic activity.¹⁷⁰ Disease may develop after long, heavy exposure; initially, it is characterized by accumulation of dust-laden macrophages around respiratory bronchioles and, later, by fiber deposits with little mature collagen; the disease appears to progress in relation to lung dust burden.^{107,170,171} Silicates are used widely as filling materials (kaolin, talc, and chlorite); insulation (mica, vermiculite); and absorbents (attapulgite, sepiolite), among other uses.¹⁷⁰ The clay minerals, talcs and mica (also called phyllosilicates because of their sheet structure),¹⁷⁰ constitute an important group.

World production and use (estimated in 1991 as 5.3 million tons for talc alone) considerably exceeds that of the asbestos minerals, which peaked at 5 million tons in the late 1970s. Before a 1989 NATO Workshop, their toxicity as a group for humans had been little studied,¹⁷⁰ although three (talc, attapulgite, and sepiolite) had been evaluated for carcinogenic risk for humans by the IARC.¹⁷⁰ The information in this section is derived from the report of this workshop¹⁷⁰ and other sources.^{2,122,172} Talc and, more often, mica particles may form the core of ferruginous bodies. In general, the nonfibrous silicates have pulmonary effects similar to those caused by coal, unless they contain fibrous forms of these minerals or are contaminated by asbestos fibers, in which case their effects are closer to those produced by asbestos. The biologic effects of silica (quartz) may be modulated by the presence of silicates.

KAOLIN PNEUMOCONIOSIS

The lesions of kaolin pneumoconiosis tend to be cellular and dust packed.¹⁷⁰ In its simple form, this pneumoconiosis is not usually associated with clinical or lung function changes, but rarely, there may be interstitial fibrosis or PMF and impairment of lung function.² In 10 surveys of kaolin-exposed work forces, the radiologic prevalence of simple pneumoconiosis (mostly small round opacities) ranged from less than 1% to 26.3%, whereas complicated pneumoconiosis and pleural changes were unusual.¹⁷² In general, prevalence was related to level and duration of dust exposure and probably contamination by other materials, including silica. Although lung cancers have been mentioned in relation to kaolin exposure,^{7,173} no cohort mortality studies have been reported.

TALC PNEUMOCONIOSIS

The lesions of talc pneumoconiosis include peribronchial and perivascular interstitial accumulations of dust-filled macrophages, ill-defined nodular lesions in which birefringent talc crystals can be seen, and foreign body granulomas.^{2,170} In general, the disease evolves slowly and PMF is infrequent; tuberculosis may complicate the condition but might reflect concomitant silica exposure. Interstitial fibrosis also may develop. A granulomatous arteritis caused by talc embolism is described in those who use an intravenous route for talc-containing drug tablets (eFig. 73-16). Pleural changes, including plaques, are common; they are usually associated with mining exposures and may be due to contamination of mine dust by fibers (tremolite or anthophyllite).^{2,170} Reactions to talc can be difficult to distinguish from those caused by silica or by asbestos, which often contaminate or even predominate in industrial grade talc.² In six surveys of talc-exposed workforces, prevalence of small opacities ranged from less than 1% to 37%, the lower rates in some studies in which exposure was to pure talc and the higher rate in long-time workers.^{172,174} In three of seven cohort mortality studies in talc-exposed workers, excess deaths were recorded from nonmalignant respiratory disease, including pneumoconiosis. In addition, an excess of respiratory cancer mortality was found in five of the seven cohorts, but these findings must be interpreted with caution because they were based on only 13 or fewer deaths

in each cohort. In four of these, coexposure to other carcinogenic agents (mineral fibers, radon, silica) could have been implicated.¹⁷² Several cases of mesothelioma were reported but all in cohorts exposed to fiber-contaminated dusts.¹⁷²

MICA PNEUMOCONIOSIS

The lesions of mica pneumoconiosis comprise dust particles surrounded by reticulin but usually with relatively little cellular reaction, although there are case reports of interstitial fibrosis¹⁵⁶ in which granulomas also have been described.¹⁷² In three surveys of mica-exposed work forces, the prevalence of radiologic pneumoconiosis ranged from 1% to 44%, the latter work force being exposed to quartz-contaminated mica.¹⁷² No mortality studies have been reported, but there has been one case report of a peritoneal mesothelioma in a mica-exposed worker.¹⁷² Vermiculite, also a mica, does not appear to be toxic to the lungs of animals. However, in four surveys of vermiculite-exposed mine workers, the prevalence of radiologic pneumoconiosis ranged from less than 1% to 18% and of pleural changes from 3% to 28%; in a processing plant, rates were higher and were related to cumulative exposure.^{170,172} Pleural effusions and pleural thickening have been reported in mica-exposed work forces but are thought to relate to amphibole contamination of vermiculite. Vermiculite mined in Libby, Montana, has been found to be contaminated with asbestos and to be associated with asbestosis, mesothelioma, and lung cancer in former miners, millers, and processors. The material has been widely used as insulation in buildings, which has raised concern for those exposed through building maintenance and renovation.¹⁷⁵ A case report of fatal asbestosis 50 years after exposure to vermiculite from Libby in a California expansion plant emphasizes the risk from even brief but intense exposure to this material.¹⁷⁶ The lung biopsy fiber analysis showed 8 million fibers per gram of dry lung, a level certainly compatible with the diagnosis of asbestosis, of which 68% were tremolite. Pleural plaques had been noted on his chest film 10 years before evidence of interstitial lung disease became apparent. A recent report highlights the effects of environmental exposure to Libby vermiculite in one of many sites outside Montana where the material has been processed.¹⁰⁵

The authors of a 1990 review¹⁷² concluded that (1) there is little evidence that occupational exposure to pure kaolin, talc, mica, or vermiculite carries any important risk for health; (2) long and heavy exposure to kaolin and mica may result in low-grade radiographic changes, but clinically important pneumoconioses in work forces exposed to these phyllosilicates are likely to be the result of contamination by silica or asbestos fibers; (3) pleural lesions are common in talc-exposed workers but are probably caused by fiber contaminants; and (4) the increased rates of lung cancer or mesothelioma recorded in several exposed work forces probably result from exposure to silica or fiber contaminants of the ore or milled products.

MAN-MADE VITREOUS FIBERS

The production of *man-made vitreous fibers* (MMVFs), including glass fibers, mineral wool, refractory ceramic fibers, and

mineral fibers such as carbon graphite, Kevlar-Aramid, silicon carbide, and aluminum oxide has increased markedly since the restriction or banning of asbestos in several countries. As with asbestos fibers, determinants of MMVF toxicity are (1) their dimensions (greatest risk with fine, long fibers < 0.25 μm in diameter and > 8 μm in length); (2) their biopersistence, which can be altered in the production process according to the end use; and (3) dose to the target organ. MMVFs differ from asbestos fibers in being more soluble, less durable, and less biopersistent along a gradient: glass > rock > ceramic fibers.¹⁵⁹ Airborne levels in plants manufacturing MMVFs are commonly lower than 1 fiber/mL and lower in most applications except the application of insulation in confined spaces.¹⁷⁷ Airborne fiber diameters, with the exception of ceramic fiber, are generally large (1 mm) and thus nonrespirable. Despite their intensely irritating effects on skin and mucous membranes, there is no firm evidence that these fibers produce lung fibrosis, pleural lesions, or nonspecific respiratory disease in humans. Refractory ceramic fibers may, however, enhance the effects of smoking in producing airway disease.^{177,178} An increased standardized mortality ratio for lung cancer in several cohorts exposed to MMVFs is now thought to have been attributable to smoking.^{159,161} Nevertheless, several agencies have recommended exposures of 0.5 to 1 fiber/mL based on apparent excess working lifetime risk for lung cancer.¹⁷⁹ There is no evidence of an increased mesothelioma risk for MMVF workers¹⁶⁰ but, as mentioned earlier, a French report suggests that mineral wool enhances the risk for mesothelioma in workers also exposed to asbestos.¹⁶²

BERYLLIUM LUNG DISEASE

BERYLLIUM: USES, HUMAN TOXICITY, AND EXPOSURES

Beryllium is a rare metal that has many applications in modern industry because of its light weight, tensile strength, high melting point (1500° C), excellent alloying properties (beryllium-copper alloys are the most widely used), good thermal and electrical conductivity, resistance to corrosion, and ability to reduce the speed of nuclear fission.¹ Major sources are Argentina, Brazil, India, Zimbabwe, South Africa, and the United States. Its toxicity for humans was first recognized in Europe in the 1930s. In the United States, an epidemic of *chronic beryllium disease* (CBD) was recognized as a result of exposure in the fluorescent light industry during the 1940s, leading to discontinuation of its use in that industry and the institution of engineering controls in other industries handling beryllium.¹ Initially, a large number of cases of acute berylliosis, an acute, toxic pneumonitis, were documented but acute cases are now uncommon. Chronic berylliosis, a disease with features similar to those of sarcoidosis, continues to be reported. Cases arise from beryllium exposure in a wide variety of industries including the manufacture of alloys, ceramics, radiographic equipment, and vacuum tubes and in the extraction and smelting of beryllium. Cases have been reported from exposure to beryllium in dental laboratories, but there is no risk to those in dental offices nor to those who wear dental crowns or other completed products. The number of indi-

viduals potentially exposed in the United States in 1987 was estimated between 30,000 and 800,000 in the following industries: aerospace, electronics, ceramics, metal, including refining of scrap metal, nuclear (reactors, weapons), telecommunications, tool and die, and welding.¹⁸⁰ Cases of berylliosis have also been reported in residents living near a beryllium manufacturing facility¹⁸¹ and in a wife who laundered her exposed husband's clothing.¹⁸² Sarcoidosis-like granulomatous lung disease in firefighters involved with rescue work at the World Trade Center is of uncertain origin and might suggest berylliosis or another environmental cause for granulomatous lung disease.¹⁸³

PATHOLOGY AND IMMUNE PATHOGENESIS

CBD is a multisystem disorder characterized by noncaseating granulomas throughout the body, although their primary manifestation is in the lung.^{2,180} On pathologic examination, CBD is characterized by the presence of a lymphocytic (helper/inducer T cells) alveolitis, as well as noncaseating epithelioid granulomas indistinguishable from those of sarcoidosis (eFig. 73-17A and B). There is a variable amount of fibroblastic activity that progresses to interstitial fibrosis as the lesions mature. Granulomatous lesions may occasionally be found in other sites, including thoracic and abdominal lymph nodes, spleen, liver, kidneys, and adrenal glands.

Beryllium enters the body by inhalation and, occasionally, via the skin, where it acts as a specific antigen (alone or as a hapten through an IL-2 receptor pathway), leading to a proliferation of specific CD4 lymphocytes, release of lymphokines, and granuloma formation.¹ Because the agent persists in the lung, its slow release over time explains the appearance and progression of disease, even without further exposure.^{1,2} There is evidence for an underlying genetic basis for susceptibility to beryllium disease, linked to a major histocompatibility complex (MHC) class II marker (*human leukocyte antigen* [HLA]-DP β -1^{Glu69}) carrier status, which adds to the effect of the process (exposure) risk factor.^{184,185} Evidence for delayed hypersensitivity to beryllium may be assessed by the *in vitro beryllium lymphocyte proliferation test* (BeLPT) on lymphocytes from blood or BAL.¹⁸⁶ Although these reactions are thought to indicate exposure and sensitization, not disease, in one series, six of eight sensitized individuals had granulomas on transbronchial biopsy.¹⁸⁷

Beryllium is considered to be a human carcinogen, especially in the presence of beryllium lung disease; in 1993, the IARC classified beryllium as a class 1 human carcinogen.¹⁸⁸

CLINICAL FEATURES

Acute beryllium disease is uncommon, with clinical features including cough, chest pain, blood-tinged sputum, crackles, and patchy airspace disease on the chest radiograph. The disorder is associated with high, and usually accidental, exposure and may present with an acute syndrome with features of the acute respiratory distress syndrome or in a subacute form with features of pneumonitis.¹⁸⁹ CBD may follow an acute beryllium pneumonitis but more usually develops without antecedent events. The clinical

features of CBD are similar to those of pulmonary sarcoidosis, although extrapulmonary manifestations including hilar and mediastinal lymphadenopathy and splenomegaly are less common.^{180,190} There may be no associated symptoms,¹⁸⁶ but symptoms often include dyspnea, cough, chest pain, weight loss, fatigue, and arthralgias. Physical signs may include crackles, but signs of lung disease are often absent. Radiographic changes may precede the development of symptoms. The usual finding is ill-defined nodular or irregular opacities (eFig. 73-18A and B, Video 73-5); hilar lymphadenopathy (see eFigs. 73-18C and D) is seen in approximately 40% of cases but is usually mild.¹⁸⁰ In the later stages of the disease, patchy fibrosis is seen, with adjacent hyperinflation or distortion and extensive honeycombing. In CBD, in advanced disease, pulmonary function usually shows a restrictive defect but, in mild or moderate disease, may show features including obstruction or an isolated reduction in DL_{CO}.¹⁹¹ The clinical course of CBD is variable. Some cases remain stable, some relapse and remit, and some progress inexorably.¹⁸⁰

DIAGNOSIS AND MANAGEMENT

The diagnosis of CBD is based on documented exposure to beryllium, evidence of lung disease compatible with the diagnosis, and a positive BeLPT performed on blood or BAL fluid.¹⁹² The BeLPT allowed for the introduction of three categories of beryllium-associated disorders: beryllium sensitization (positive blood or BAL BeLPT but negative biopsy), subclinical beryllium disease (positive BeLPT and biopsy but no clinical or radiologic features of the disease), and chronic berylliosis (positive BeLPT and biopsy with clinical and radiologic features of disease).¹⁹²

Given the potentially long latency time for CBD and despite the generally lower exposures since the 1950s and its decreasing frequency, CBD still should remain in the differential diagnosis of sarcoidosis. Clusters of sarcoidosis in a workplace should alert the clinician to the possibility that these represent examples of chronic berylliosis. In this context, note should be made of the wide range of occupations associated with potential exposure to beryllium.

The most important step in case management is complete cessation of further exposure to beryllium, and this advice should also be given to exposed workers with a positive BeLPT, even in the absence of clinical and radiologic signs of disease, because of the high prevalence of lung granulomata associated with that finding.¹⁸⁷ Corticosteroid therapy has been recommended in CBD, and long-term steroid therapy is believed to alter the course of the disease favorably, although there are no reports of permanent cure.

HARD-METAL DISEASE

Hard-metal disease, first described in Germany in the 1940s, has now been reported from many countries. Hard metal is manufactured by a process called *sintering*, the fusing of a powder together at high temperature. In making hard metal, a powder of tungsten carbide powder (often with tantalum carbide or titanium carbide added) and 10% cobalt is pressurized and heated to 1500° C.¹ The resultant “hard metal” has diamond-like hardness, extreme strength,

and heat resistance; because of these qualities, hard-metal products have wide application in industry as drill tips (from dental to engineering drilling and diamond polishing), cutting and tunneling tools, grinding wheels, molds, jet engines, and ferromagnets. Humans are exposed in the manufacturing of hard-metal products and in their maintenance and use. The grinding of sintered pieces generates high dust and cobalt concentrations.

Work-related illness in hard-metal workers may be acute (rhinitis and asthma), subacute (hypersensitivity pneumonitis), or chronic (diffuse and progressive interstitial fibrosis).¹⁹³ The interstitial fibrosis is characterized by unusual multinucleated giant cells comprising alveolar type II cells and macrophages (eFig. 17-19), which can sometimes be recovered from BAL. The interstitial lung disease that has been described with exposure to both tungsten carbide products and in diamond polishers¹⁹⁴ is thought to be a hypersensitivity pneumonitis to cobalt, which reacts with metallic carbides to produce active oxygen species.¹⁹⁵ A genetic association with some HLA-DP alleles may also be implicated.¹⁹⁶ This affords a plausible explanation of why only a small proportion of those exposed develop disease. A 1998 industry-wide cohort study in 10 facilities in France documented an increased mortality from lung cancer associated with simultaneous exposure to cobalt and tungsten carbide.¹⁹⁷ A review of workplace surveys indicates that interstitial disease is rare, whereas airway diseases including bronchitis and asthma are more frequent.^{193,198} Both interstitial (eFig. 73-20 and Video 73-6) and airway disease may be seen in the same individual. Diagnosis is based on an exposure history, a compatible clinical presentation, and pathologic and mineralogic features on biopsy.^{193,199} Both tungsten carbide and cobalt have now been identified in the centrilobular fibrotic lesions associated with hard-metal lung disease.²⁰⁰ Prompt diagnosis and removal from exposure may reverse acute disease, including asthma, and prevent the development of chronic disease. There have been several reports of response to withdrawal from exposure and treatment with corticosteroids.² Prevention requires control of exposure; for monitoring workforce exposure, the measurement of urinary cobalt may be useful.

SILICON CARBIDE (CARBORUNDUM) PNEUMOCONIOSIS

Carborundum pneumoconiosis is associated with exposure in the manufacture of carborundum, a silicon carbide of extreme hardness used as an abrasive. Under current exposure levels, this is generally a mild and nonprogressive disorder.²⁰¹ There is, however, some evidence that those exposed to this material, which has a silica and a fibrous component, are at risk for pneumoconiosis associated with lung dysfunction^{202,203} and, possibly, for lung cancer.²⁰⁴

NEW PNEUMOCONIOSES

Lung diseases associated with exposure to metal-working fluids²⁰⁵; nylon, rayon, and polypropylene flock²⁰⁶; indium;

popcorn flavoring (diacetyl)²⁰⁷; and nano-particles have been described. A recent review details these diseases and lung disease associated with exposure to the burning and collapse of the World Trade Centers in New York.²⁰⁸

Key Points

- The population exposed to dust in the workplace is so large that an occupational history, including remote occupations, should be part of every respiratory assessment.
- Chest radiography and occupational history are the mainstays for the diagnosis of pneumoconiosis, although CT and lung biopsy may be necessary, especially for asbestosis.
- Because of the many interactions between smoking and dust, it is important to implement smoking-cessation programs in the workplace.
- Workers exposed to dust are at risk for developing *chronic obstructive pulmonary disease* (COPD) and chronic bronchitis. In some cases, they are also at risk for fibrosis and lung cancer.
- Silicosis is a risk in a wide range of new and older but less classic industries such as concrete rehabilitation, stone carving, and the sandblasting of denim jeans.
- Silica dust is a risk factor for tuberculosis and other mycobacterial lung diseases, lung cancer, COPD, and connective tissue diseases.
- Coal mining is ubiquitous and, with mechanization, continues to expose underground and surface miners to large amounts of dust; high rates of coal workers' pneumoconiosis are seen especially in small mining operations.
- Asbestos-related diseases will be seen for many decades because of the long latent period between exposure and disease and because asbestos is still widely encountered.

eFigure 73-10 Asbestosis. Frontal chest radiograph in a patient with asbestos exposure shows bilateral calcified pleural plaques (arrows) and obscuration of the left cardiac border (arrowheads), representing the "shaggy heart border sign" in asbestosis. (Courtesy Michael Gotway, MD.)

eFigure 73-11 Asbestosis. A–C, Axial prone high-resolution CT of the lung through the bases in a patient with asbestos exposure shows bilateral, subpleural linear and reticular opacities (*arrowheads*) consistent with asbestosis. (Courtesy Michael Gotway, MD.)

eFigure 73-12 Asbestosis. A, Frontal chest radiograph in a patient with asbestos exposure shows bilateral calcified pleural plaques (*arrows*) and faint basal linear and reticular abnormalities (*arrowheads*) suggesting possible fibrotic lung disease. The heavy pleural calcification limits assessment. B, Axial chest CT through the lung bases shows pleural calcifications (*large arrows*) and peripheral linear and reticular opacities (*arrowheads*) with mild traction bronchiectasis (*small arrow*), confirming fibrotic lung disease. (Courtesy Michael Gotway, MD.)

eFigure 73-13 Asbestos-induced pleural plaques and rounded atelectasis. **A**, Frontal chest radiograph in a patient with asbestos exposure shows a poorly defined right lower lobe opacity (arrows). **B–D**, Axial chest CT through the lung bases shows calcified and non-calcified pleural plaques (black arrowheads) and confirms the right lower lobe subpleural mass (arrows). The mass is in contact with abnormal pleura and is associated with a spiraling configuration of the bronchovascular bundles (white arrowheads) leading to the mass, as well as right lower lobe volume loss—these features are consistent with rounded atelectasis (see [Video 73-4](#)). (Courtesy Michael Gotway, MD.)

eFigure 73-14 Diffuse pleural thickening related to asbestos exposure. **A–D**, Axial prone chest CT in soft tissue (**A–C**) and lung (**D**) windows shows extensive contiguous pleural thickening (arrowheads **A–C**) extending continuously from the posteromedial thorax along the right lateral thorax. Image displayed in lung windows (**D**) shows other pulmonary parenchymal findings associated with asbestos exposure, such as parenchymal bands (arrow) and a subpleural line (arrowheads). (Courtesy Michael Gotway, MD.)

eFigure 73-15 Pleural plaque. The whitish plaque has been resected along with surrounding tissue and is viewed en face. Its gross appearance has been likened to that of candle wax drippings. (From Butnor KJ, Roggli VL: *Pneumoconioses*. In Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, pp 311–338, Fig. 9-31).

eFigure 73-16 Talc granulomatosis. Axial chest CT in an injection drug user shows numerous small basal centrilobular opacities (arrowheads) found on biopsy to represent small talc granulomas. (Courtesy Michael Gotway, MD.)

eFigure 73-17 Chronic beryllium disease. **A**, The presence of numerous granulomas is characteristic of *chronic beryllium disease* (CBD) (arrows). **B**, In addition to granulomatous inflammation, there is a chronic interstitial inflammatory infiltrate. (From Butnor KJ, Roggli VL: *Pneumoconioses*. In Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, pp 311–338 [Figs. 9-91 and 9-93].)

Figure 73-18 Chronic beryllium disease. **A** and **B**, Axial chest CT shown in lung windows shows subpleural nodules (*arrowheads*) associated with central bronchovascular thickening and architectural distortion. The appearance resembles sarcoidosis. **C** and **D**, Axial chest CT shown in soft tissue windows shows mild, symmetric, bilateral calcified lymph node enlargement (*arrows*). An uncalcified, mildly enlarged left retrobronchial lymph node (*arrowhead*, **C**) is present. The appearance is identical to sarcoidosis. [Video 73-5](#) shows the upper lobe distribution of the pulmonary parenchymal abnormalities to advantage. (Courtesy Michael Gotway, MD.)

Figure 73-19 Hard-metal pneumoconiosis. **A**, At low magnification, the interstitium appears widened, accompanied by alveolar filling. **B**, This example demonstrates interstitial pneumonia with hyperplastic type II pneumocytes (*arrow*) and multinucleate giant cells (*arrowheads*) in alveolar spaces. (From Butnor KJ, Roggli VL: *Pneumoconioses*. In Leslie KO, Wick MR, editors: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, pp 311–338, Figs. 9-82 and 9-83.)

Figure 73-20 Hard-metal lung disease. **A–C**, Axial chest CT (**A** and **B**, prone, **C**, supine) in a 26-year-old man who was a saw sharpener shows upper lobe predominant linear and nodular opacities (*arrowheads*) associated with mild architectural distortion. Basal subpleural bands (*arrows*, **C**) are noted. Chest CT video ([Video 73-6](#)) shows the upper lobe distribution of the pulmonary parenchymal abnormalities to advantage. Extensive subpleural cystic change is present. The patient was a nonsmoker, and his urinary cobalt levels were abnormally elevated. Lung biopsy showed numerous foamy macrophages and multinucleated giant cells. (Courtesy Michael Gotway, MD.)

INTRODUCTION

Catastrophic air pollution events in the Meuse Valley of Belgium (1930), Donora, PA (1948), and London (1952) arose when air stagnation caused high levels of ambient pollutants, especially sulfur dioxide and particles. In each case, there was a marked increase in respiratory symptoms and mortality. These “fog disasters” provided incontrovertible evidence that air pollution can have immediate lethal consequences. Since this time, scientific investigations have uncovered myriad adverse respiratory health effects of air pollution, ranging from asthma exacerbation to respiratory mortality.

The respiratory system, because it is the portal of entry for air pollutants, suffers the major consequences of air pollution. This chapter reviews the key air pollutants, which are termed *criteria pollutants* by the U.S. *Environmental Protection Agency* (EPA), and how they affect the airways and lungs (Table 74-1). Both indoor and outdoor air pollution are considered. Respiratory health conditions that are most strongly linked with air pollution are reviewed.

AIR POLLUTANTS

POLLUTANTS—WHAT THEY ARE AND WHY THEY MATTER

Air pollution involves the contamination of the atmosphere by chemicals, particles, or biologic materials that causes human morbidity and mortality, damages other living organisms such as plants, or adversely affects the natural environment such as by reducing visibility. Pollutants can be emitted from mobile sources (e.g., vehicles), stationary

sources (e.g., factories, power plants, refineries), and indoor sources (e.g., building materials, gas stoves, passive smoking, cleaning products).¹⁻³

Toxic air pollutants (air toxics) are a subset of air pollutants that may cause cancer or other serious health effects such as birth defects. These substances, such as benzene and cadmium, produce primarily nonrespiratory effects despite entering the body via the respiratory tract.

The major types of air pollutants affecting the respiratory system are *particulate matter* (PM), *sulfur dioxide* (SO₂), *nitrogen dioxide* (NO₂) and *ozone* (O₃) (Table 74-2). The principal sources of these pollutants are mobile and stationary sources. Ozone is a secondary pollutant that arises from the action of sunlight on nitrogen oxides and hydrocarbons present in motor vehicle exhaust. It is a major component of photochemical pollution or “smog.” The respiratory health effects of these pollutants are considered later in the chapter. Two other air pollutants, *carbon monoxide* (CO) and lead, which also enter via the respiratory tract, have primarily nonpulmonary toxicity and are not considered further in this chapter.

Indoor air quality has assumed increasing importance. As levels of outdoor ambient air pollution have decreased in many areas throughout the United States, the relative impact of indoor air pollution has increased. Moreover, North American residents spend the majority of their time indoors, increasing their exposure to indoor air pollutants.^{4,5} At the same time, changes in home and office building construction have resulted in lower air exchange rates, increasing the levels of pollutants emitted indoors.⁶ In the developing world, indoor air pollution due to biomass smoke from domestic cooking and heating is a major source of morbidity and mortality.⁷

GENERAL PROPERTIES, SOURCES, AND DISTRIBUTION OF POLLUTANTS

PM, sulfur oxides, NO₂, and O₃ are the most widely encountered pollutants that cause adverse pulmonary health effects.¹⁻³

PM is an important pollutant. In the western United States and many other areas of the world, particulate pollution is not driven by the combustion of sulfur-containing fuels. Atmospheric particulate air pollution arises from a variety of sources, including both natural (e.g., sea spray, windblown dust) and synthetic (e.g., power plants, motor vehicles) sources.^{8,9} Moreover, particulate material that enters the atmosphere can be primary (particles emitted directly) or secondary (particles formed by complicated chemical reactions happening in the atmosphere and involving gas-phase precursors such as SO₂ and nitrogen oxides). In North America, secondary particles comprise most of the fine-particle pollution.

Table 74-1 National Primary Air Quality Standards in the United States (Criteria Pollutants)

Pollutant	Standard*	Averaging Period
Particulate matter < 10 µm (PM ₁₀)	150 µg/m ³	24 hr
Particulate matter < 2.5 µm (PM _{2.5})	12 µg/m ³ 35 µg/m ³	1 yr 24 hr
Sulfur dioxide	75 ppb (214 µg/m ³) 500 ppb (1430 µg/m ³)	1 hr 3 hr
Nitrogen dioxide	100 ppb (188 µg/m ³) 53 ppb (100 µg/m ³)	1 hr 1 yr
Ozone	75 ppb (100 µg/m ³)	8 hr
Lead	0.15 µg/m ³	Rolling 3-mo average
Carbon monoxide	9 ppm (10 mg/m ³) 35 ppm (40 mg/m ³)	8 hr 1 hr

*Where two standards are listed, the first is the primary air quality standard set by the U.S. Environmental Protection Agency to protect health. The second standard listed is the so-called secondary standard, which is set to protect welfare.

Ppb, parts per billion; ppm, parts per million.

In epidemiologic studies, researchers have defined the size of particles in terms of aerodynamic diameter because most particles have irregular shapes with geometric diameters that cannot be easily measured. The aerodynamic diameter is the diameter of a perfect sphere of unit density (1 g/mL) that has the same aerodynamic properties (e.g., settling velocity) as the particle in question. Larger particles are filtered in the nose and throat, but particles less than 10 µm in diameter (i.e., PM₁₀) can be deposited in the respiratory tract.^{8,9} Fine particles, which are less than 2.5 µm in diameter (PM_{2.5}), penetrate to the alveoli, and ultrafine particles (PM_{0.1}) can pass through the alveoli and spread to other organs.

Size also determines how far particles travel and persist in the environment. Fine particles can travel for long distances and remain in the atmosphere for days to weeks; “coarse” particles (>2.5 to 10 µm) travel for rather short distances and have atmospheric half-lives of minutes to hours.¹⁰ Ultrafine particles are typically generated from combustion processes and have short atmospheric half-lives. For example, the concentration of ultrafine particles emitted from motor vehicles on a major roadway has a rapid falloff with distance from the roadway; the concentration is back down to the background level at or beyond 300 m.¹⁰

Fine particles (PM_{2.5}) are composed mainly of varying amounts of water and several major components (sulfates, acids, nitrates, elemental carbon, organic carbon, and trace metals) depending on sources.¹¹ They are directly emitted during combustion but are also formed from gases by nucleation, condensation, or liquid-phase reactions. Coarse particles (PM_{10-2.5}) are composed primarily of crustal (rock, soil), biologic (pollen, spores), and industrial components; they are formed primarily by mechanical processes that produce small particles from larger particles.

SO₂ is produced by the combustion of sulfur contained in fossil fuels such as coal and crude oil. The major sources of SO₂ pollution are power plants, oil refineries, smelters, and paper pulp mills. In the United States, SO₂ levels are generally higher in the Northeast and Midwest because sulfur-containing coal is used in power plants. Sulfur dioxide itself is a clear, highly water-soluble gas, so it is effectively absorbed by the mucosal surfaces of the upper airways. A small proportion of inhaled SO₂ reaches the distal regions

Table 74-2 Major Pollutants Associated with Adverse Pulmonary Effects

Pollutant	Outdoor Sources	Indoor Sources	Adverse Effects
Particulate matter	Motor vehicle exhaust, power plants	Tobacco and wood smoke	Exacerbations of asthma and chronic obstructive pulmonary disease, increased cardiopulmonary mortality
Sulfur oxides	Power plants, oil refineries, smelters	Kerosene space heaters	Bronchoconstriction
Nitrogen oxides	Motor vehicle exhaust, power plants, oil refineries	Gas stoves and furnaces, kerosene space heaters	Airway injury (respiratory bronchiolitis), impaired lung defenses, enhanced response to allergens
Ozone	Motor vehicle exhaust	Aircraft cabins, welding, copiers, ozone generators	Airway injury (respiratory bronchiolitis), decreased lung function, exacerbations of asthma, enhanced response to allergen
Radon	None	Residential basements	Lung cancer
Polycyclic aromatic hydrocarbons	Diesel exhaust	Tobacco smoke	Lung cancer

of the lungs, but susceptible persons such as those with asthma may still suffer adverse respiratory health effects.^{12,13} The SO₂ released into the atmosphere does not, however, remain uniquely in the form of a gas; rather, it undergoes chemical reactions with water, trace metals, and other pollutants to form particulate aerosols. The nature of particles generated from sulfur-containing fuels varies geographically, but sulfuric acid and various metallic, acidic, and ammonium sulfates are commonly present. The mixture of sulfur oxides and small particles may be blown great distances from its source, undergoing continuous transformation from gas to particle phase and ultimately becoming “acid rain” capable of profoundly affecting flora and fauna.¹⁴

NO₂ is rapidly generated from nitrogen oxides, which are produced whenever there is combustion, and motor vehicles and power plants are the major sources of this pollutant. The areas with the highest concentrations of NO₂ tend to be the downtown cores of large cities where there are major roadways and traffic congestion. Because NO₂ tracks well with traffic emissions, it is often considered a marker of traffic-related air pollution in epidemiologic studies. NO₂ reacts with oxygen to generate O₃ and nitric oxide, but this is a bidirectional reaction so that O₃ levels tend to be lower in areas where NO₂ is concentrated. Thus, O₃ levels tend to be lower in neighborhoods adjacent to major roadways.

O₃ arises primarily from the action of sunlight on emissions from internal combustion engines of motor vehicles.¹⁵ The most important of these emissions are unburned hydrocarbons (so-called *volatile organic compounds* or VOCs) and nitrogen oxides. In the atmosphere farther away from traffic sources, ultraviolet irradiation of the mixture of VOCs and NO₂ results in a complex series of chemical reactions, producing O₃, alkyl nitrates, peroxyacyl nitrates, alcohols, ethers, acids, peroxyacids, and other organic and inorganic compounds that exist in both gas and particulate aerosol phases.¹⁵ This mixture of pollutants typifies the “smog” found in areas with large numbers of automobiles and abundant sunlight, such as the Los Angeles basin.

Because O₃ and NO₂ are the gases present in the highest concentration in smog and they clearly cause toxic effects in animals and humans, they have been the oxidant pollutants most extensively studied. Both gases are relatively insoluble and poorly absorbed by the upper airways. A high proportion of the inhaled dose therefore reaches the peripheral portion of the lungs and can cause injury at any site from the upper airways to the alveoli.^{16,17}

Outdoor urban air contains a number of known lung carcinogens, including *polycyclic aromatic hydrocarbons* (PAHs), *n*-nitroso compounds, and asbestos. The concentrations of these carcinogens in ambient air, however, are quite low. Diesel exhaust, in particular, contains particles with PAHs as constituents. Epidemiologic studies have provided consistent evidence of an excess risk of lung cancer in workers exposed to diesel exhaust; it is listed by the International Agency on Cancer Research as a known human carcinogen.^{18–21} Several large population-based epidemiologic studies have also linked lung cancer to long-term exposure to PM, SO₂, and O₃ pollution.^{22–26}

Although most attention has been given to pollutants present in outdoor air, it is now apparent that elevated

concentrations of airborne contaminants are common inside homes, public buildings, and other indoor micro-environments.^{6,27} In developed countries, there are point sources of pollution indoors, such as secondhand tobacco smoke and gas stove use, that greatly increase the concentration of pollutants compared with outdoor air. In developing countries, biomass fuels are still burned indoors in poorly efficient stoves for cooking and heating. Biomass smoke is a mixture of gases and PM that is similar to tobacco smoke with the exception that it does not contain nicotine. Both indoor and outdoor pollution must be considered when assessing the total health effects of air pollution.

MECHANISMS OF DEFENSE AGAINST AIR POLLUTION-RELATED RESPIRATORY EFFECTS

The respiratory system, which encounters myriad particles and gases daily, has evolved an effective defense system for removing impurities from inhaled air. The various mechanisms of defense are interrelated and work in a coordinated manner. A perturbation of any defense mechanism, whether because of congenital deficiency, disease, or the effect of an inhaled pollutant itself, may result in the breakdown of the coordinated defense system and the development of disease.

DEPOSITION OF AND CLEARANCE OF PARTICLES (see Chapter 11)

The size of particles determines their site of deposition in the respiratory tract.²⁸ Large particles (diameter > 10 µm) are efficiently removed in the nose by simple filtration via the cilia. Those particles that are not removed by filtration will largely be deposited by a process termed *impaction*. The pathway through the nose, mouth, and branching airways is tortuous. Because inhaled particles cannot easily change direction to follow the abrupt changes in the pathway of airflow, they impact on the mucosa of the upper and lower respiratory tract. Airway bifurcations are especially prone to particle impaction. The complementary mechanisms of filtration and impaction are efficient, so few particles more than 10 µm reach the lower respiratory tract.

Smaller particles are less affected by filtration and impaction; the sites of their deposition are more determined by the processes of sedimentation and diffusion.²⁸ Sedimentation is the tendency for particles to fall at a constant rate under the influence of gravity. It is strongly influenced by particle density, particle diameter, and the viscosity of the surrounding gas. As air moves deeper into the lung, the airflow rate decreases and particles fall out of the air stream under the influence of gravity. Sedimentation is the predominant mechanism for deposition of particles of intermediate size (0.5 to 3.0 µm) in the smaller bronchi, bronchioles, and alveoli.

The smallest particles (<0.5 µm), however, are deposited by the mechanism of diffusion. These particles have random (Brownian) motion and will impact the airway mucosa in

the terminal bronchioles and alveoli, removing them from the stream of inspired air.

The pattern of breathing can influence the deposition of particles. A higher respiratory rate increases the velocity of airflow, promoting impaction of particles in the more proximal airways. Conversely, increased tidal volume results in deeper lung penetration by particles; when the respiratory rate is slow, there is more time for diffusion and sedimentation to deposit particles in the distal airways and alveoli.

After particles are deposited in the tracheobronchial tree, cough and mucociliary clearance are the most important mechanisms of defense. Cough is most effective for clearing particles that are deposited in the larger, more central airways. It is provoked by stimulation of afferent nerves that are most densely present in the mucosa of the larynx and branching points of the tracheobronchial tree, at which particles are most likely to be deposited.²⁹

The “mucociliary escalator” is a critical system for clearing particles that are deposited in the tracheobronchial tree; it operates over the respiratory tract from the proximal trachea to the terminal bronchioles. The mucus blanket is the product of secretion by goblet cells and serous cells of the epithelium and by the mucus cells and serous cells of the submucosal glands. The mucus blanket is propelled mouthward by the coordinated beating of epithelial cell cilia. The effective removal of particles by the mucociliary system thus requires secretion of glycoproteins by specialized secretory cells, maintenance of liquefaction by the transport of water and solute by airway epithelial cells, and coordinated function of airway cilia. Impairment of any of these functions, whether by congenital or acquired diseases affecting mucus or water secretion (e.g., cystic fibrosis, chronic bronchitis) or ciliary function (e.g., dysmotile cilia syndrome), leads to longer residence of particles in the airway and a greater likelihood of adverse health effects.

Some particles will be deposited in the distal airway and alveoli, beyond the reach of the mucociliary escalator. The central mechanism for clearing these particles involves the alveolar macrophage, which phagocytoses particles that are deposited in the gas-exchanging parts of the lung and either digests them or migrates to the respiratory bronchiole and ascends the mucociliary escalator. A smaller number of particle-laden macrophages migrate to peribronchial or perivascular connective tissue, which is a slow method of clearance that takes many weeks. Because macrophages are the primary phagocyte for inhaled PM, the carbon content of macrophages has been used as a biomarker of exposure to particulate pollution in epidemiologic studies.³⁰

GASES—DEPOSITION AND DAMAGE ARE FUNCTIONS OF SOLUBILITY

For gaseous pollutants such as O₃, NO₂, and SO₂, the site of deposition in the respiratory tract is largely a function of water solubility. For highly soluble gases, the nose serves an important defensive function because the air inhaled transnasally is passed over the large, irregular surface of the turbinates. The promotion of turbulent flow prolongs contact with the mucosal surface, increasing adsorption. Under conditions of quiet breathing, when most air is inspired transnasally, the concentration of SO₂ that reaches

the glottis is less than 2% of the concentration inspired at the nose.³¹ The more rapid the inspiratory flow rate, the smaller the proportion of SO₂ removed. Furthermore, the mouth is substantially less efficient at absorbing gases than is the nose, and the proportion of air inhaled through the mouth increases as the ventilatory demands of exercise rise. Therefore, the dose of a soluble pollutant delivered to the lower airways is increased by exercise for three reasons: the inspiratory flow is higher, the proportion inhaled through the mouth is increased, and the total quantity inhaled over time is greater. The importance of the level of ventilation, which depends on the level of exercise, and of the oral-nasal distribution of breathing has perhaps best been shown in studies of the bronchoconstrictor response to SO₂, in which the responses are greatest during oral breathing and smallest during nasal breathing.³² In addition, people with obstructive nasal disease also appear to be at greater risk for adverse respiratory effects of soluble pollutant gases.

OXIDATIVE STRESS

Air pollution, especially particles and O₃, can increase the oxidative burden to the lung. To minimize oxidant damage to biologic molecules, the human lung has an integrated antioxidant system of enzymatic and expendable soluble antioxidants. This system includes several antioxidant defense mechanisms that detoxify reactive products or convert them to products that are quenched by other antioxidants. If the oxidant burden is sufficiently great, the reactive species may overwhelm or inactivate the antioxidant system. An imbalance between the production of *reactive oxygen species* (ROS) and reactive nitrogen species and antioxidant capacity leads to a state of “oxidative stress” that contributes to the pathogenesis of several respiratory diseases.^{33–35}

When imbalance exists, the excess oxygen species induce a cellular stress response that activates a number of the redox-sensitive signaling cascades. This initial response is mediated in large part through the transcription factor nuclear factor erythroid 2–related factor 2, which leads to transcriptional activation of more than 200 antioxidant and detoxification enzymes that are collectively known as the phase 2 response.³⁶ Examples of phase 2 enzymes include heme oxygenase 1, glutathione-S-transferase isoenzymes, NADPH quinone oxidoreductase, catalase, superoxide dismutase, and glutathione peroxidase. If phase 2 responses fail to prevent a further increase in ROS production, major cellular components, including membrane lipids, protein, carbohydrates, and DNA, will be damaged and inflammation and tissue damage may ensue.

Oxidative stress-induced proinflammatory effects are mediated by the redox-sensitive mitogen-activated protein kinase and nuclear factor-κB cascades that are responsible for the expression of cytokines, chemokines, and adhesion molecules.³⁷ Cytotoxic effects are associated with mitochondrial membrane damage, which leads to release of factors that induce apoptosis of lung cells.³⁸ Pathophysiologic consequences of pollutant-induced oxidant injury include airway inflammation leading to clinical exacerbation of asthma, increased susceptibility to infection, enhanced allergic responses, and, if repetitive or chronic, airway remodeling.

METHODS OF STUDYING THE HEALTH EFFECTS OF AIR POLLUTION

In order to develop sound public policy aimed at protecting the public from the adverse health effects of pollutants, scientific studies are necessary both to elucidate the health effects of various pollutants and to define the threshold level at which the risk substantively increases. The scientific basis of public policy is based on several lines of evidence: epidemiologic studies of the association between air pollution and disease in the population, controlled human exposure studies conducted in the laboratory, studies of the effects of pollutants on lung structure and function in animals, and in vitro studies of toxicity. Each of these study designs has advantages and disadvantages, and none alone can provide irrefutable proof of harmful effects from a particular pollutant under naturalistic conditions of exposure (Table 74-3). Air quality standards are based, therefore, on the coherence of evidence provided by epidemiologic, clinical, animal, and in vitro research and are set to provide a margin of safety to protect susceptible subgroups of the general population.

EPIDEMIOLOGIC STUDIES

Epidemiologic studies have a major role in the evaluation of air pollution-related health effects because they involve “real-world” exposures of human subjects. The strengths of epidemiologic studies include the ability to evaluate a wide array of health effects and representative sampling of the larger population. These studies, however, have to address issues of confounding and other sources of bias. Moreover, epidemiologic studies, although they play a key role in support for regulatory intervention, do not provide mechanistic data; human, animal, and cellular toxicologic data are required to understand mechanistic pathways.

For each putative pollution-related health effect, evidence must be compiled from published literature, synthesized, and evaluated for the likelihood of a causal effect. Typically, the guidelines for evaluating whether a particular pollutant (e.g., PM) causes a specific respiratory disease

(e.g., *chronic obstructive pulmonary disease* [COPD]) are those introduced by Sir Austin Bradford Hill³⁹ and used by the U.S. Surgeon General beginning in 1964. These include strength of the association, consistency of the association, specificity of the association, temporal relationship, coherence, biologic plausibility, and exposure-response gradient. Using this approach to evaluate the strength of the evidence provides a sound basis for regulatory decisions.

The issue of confounding must be addressed in epidemiologic studies of air pollution-related health effects. It is often difficult to be sure that all confounders (e.g., cigarette smoking, occupational exposures, socioeconomic status) have been identified and controlled. The use of daily time-series studies that correlate daily average air pollution levels (e.g., PM_{2.5}) with daily counts of a health outcome (e.g., deaths) is one method that provides good control of confounders that do not change over relatively short time periods.^{40,41}

Another difficulty with epidemiologic studies is that most outdoor environments include a complex mixture of pollutants. Assessing the effects of individual pollutants, one by one, might miss the effects of the mixture. A related issue is “multicollinearity,” which arises because air pollutant concentrations are correlated with one another, making it difficult to parse out the individual health effects of each pollutant. Sophisticated statistical modeling attempts are used to address these potentially confounding issues, but they remain challenges to valid inferences.^{42,43,43a}

Another major challenge to air pollution epidemiologic studies is exposure assessment. Many studies estimate individual exposure by mapping each individual subject’s home (and sometimes schools or workplaces) relative to stationary pollution monitors. Recent advances have also allowed investigators to conduct personal monitoring of exposure to specific pollutants, but expense and other logistical considerations may make this infeasible.⁴⁴ Choosing the metric of exposure that is most relevant to disease causation requires careful consideration. With O₃, for example, the 8-hour average from 10 AM to 6 PM may be most appropriate because the EPA air quality standard uses an 8-hour averaging time and these hours reflect the impact of photochemistry on O₃ precursors emitted from motor vehicles during the morning commute. In contrast, shorter peak exposures would be more appropriate for assessing the

Table 74-3 Methods for Studying Air Pollution

Method	Strengths	Weaknesses
Epidemiologic study	<ul style="list-style-type: none"> Representative sample of general population Naturalistic exposure Broad range of pollutants Wide range of health outcomes Study of susceptible subgroups 	<ul style="list-style-type: none"> Chance, bias, confounding are threats to study validity Difficulty separating effects of individual pollutants when present as multipollutant mixtures Usually no information on biologic mechanisms
Controlled human exposure study	<ul style="list-style-type: none"> Rigorous experimental design Elimination of bias and confounding Systematic control of exposure levels Study of susceptible subgroups 	<ul style="list-style-type: none"> Acute effects do not necessarily predict chronic effects Limited range of exposures and outcomes evaluated
Animal study	<ul style="list-style-type: none"> Best method for evaluating impact of pollutants on structure and function of lung Dose-response relationship (from minimal level producing health effects to death) 	<ul style="list-style-type: none"> Large interspecies response to pollutants Applicability to humans often uncertain
In vitro study	<ul style="list-style-type: none"> Elucidate cellular mechanisms Rigorous experimental control 	<ul style="list-style-type: none"> Limited to available cell lines Applicability to intact human organism often uncertain

effect of SO₂ on exacerbations of asthma. Whether a time “lag” between onset of exposure to the pollutant and onset of the health outcome (e.g., one or several days) should be considered is also an important question.

CONTROLLED HUMAN EXPOSURE RESEARCH

Experimental studies expose human subjects to pollutants under carefully controlled conditions. Such studies can rigorously evaluate the impact of a single pollutant or a mixture such as diesel exhaust on acute responses such as lung function or airway inflammation. In addition to documenting the acute health effects of pollution, controlled human exposure studies can evaluate the minimal concentration of a pollutant that causes reduction in lung function or other acute responses. These studies can also evaluate the effects of pollutants on susceptible subgroups of the population, such as on adults with asthma. Moreover, measurement of biomarkers of inflammation, oxidative stress, and other pathophysiologic processes can provide mechanistic insights.

A major advantage of controlled human exposure studies is the (near) elimination of confounding and bias because exposures are experimentally induced and carefully controlled. Because these studies evaluate acute effects, however, they cannot, by themselves, be easily extrapolated to the effects of more chronic or recurrent exposure. The finding that a brief exposure to O₃ causes acute decrements in lung function does not, for example, necessarily indicate that prolonged or repeated exposure will lead to the development of COPD. However, controlled human exposure studies, when combined with epidemiologic and animal toxicologic studies, can provide important data for establishing the causal effect of pollution on a respiratory health outcome.

ANIMAL RESEARCH

Animal studies offer the most effective way to investigate the impact of air pollution on lung structure. In addition, animal studies permit assessment of the effects of a range of concentrations so that a dose-response curve can be constructed for outcomes ranging from the first measurable change in lung function or structure until death. Animal studies also afford a unique opportunity to dissect the pathogenetic mechanisms of pollution-related health effects.

The major limitation of animal studies is the large interspecies variations in response to pollutants. As such, applicability of animal studies to humans, especially for dose-response relationships, may not always be clear. Rodents, for example, can tolerate relatively high levels of O₃ without developing structural injury to the lungs, whereas rhesus monkeys develop injury at levels approaching ambient concentrations.⁴⁵ Moreover, common human lung diseases, such as asthma and cystic fibrosis, have not been fully reproduced in animals, precluding study of these susceptible subgroups for pollution-related effects.

IN VITRO RESEARCH

Exposure of cell cultures to specific air pollutants has helped to elucidate the mechanisms of lung injury, inflammation,

and other adverse respiratory health effects. Specifically, cell culture systems have been used to study the impact of particulate and other air pollutants on inflammatory cytokines, oxidative stress, DNA damage, and cytotoxicity.⁴⁶⁻⁵² Cultures of bronchial and alveolar epithelial cells, monocytes, dendritic cells, and other cell lines have been useful for studying the mechanisms of air pollution on the respiratory system.^{52a}

AIR POLLUTION STUDIES—PUTTING IT ALL TOGETHER

In sum, there is no single study design or discipline that can establish the health effects of air pollution and provide the basis for regulation. Epidemiologic studies are required because they evaluate the impact of real-world air pollution on respiratory health outcomes among the general population. The limitations of epidemiologic studies usually mean that coherence of epidemiologic findings with those of experimental data from controlled human exposure, animal, and in vitro studies is required to provide a sufficient weight of evidence to support regulatory policy.

INDOOR AIR POLLUTION

Indoor air quality has been increasingly recognized as an important determinant of human health. As levels of outdoor ambient air pollution have decreased throughout the developed world, and because residents of these countries spend the majority of their time indoors, the relative impact of indoor air pollution has increased.⁵ To characterize personal exposure to air pollution, indoor air quality must be taken into account (Table 74-4).

SOURCES OF INDOOR POLLUTION

The concentrations of indoor air pollutants depend on both indoor and outdoor emission sources (Fig. 74-1).^{6,27,53} Outdoor emission sources determine outdoor pollution concentrations, which, in turn, affect indoor air quality.⁵⁴ The degree of penetration of outdoor pollution into the indoor environment depends largely on the rate of air infiltration from outdoors to indoors.⁵⁵ The rate of air infiltration is a complex function of the “tightness” of building construction and insulation, building location and orientation,

Table 74-4 Indoor Air Pollutants

Category of Pollutant	Indoor Pollution Source
Combustion (e.g., NO ₂ , CO, PM _{2.5} , PAHs)	Secondhand smoke Gas stoves, ovens, heaters, and fireplaces Wood smoke (stoves, fireplaces) Kerosene heaters Candles and incense
Building materials (e.g., formaldehyde, volatile organic compounds)	Plywood Particle board Carpeting Paints
Cleaning materials (e.g., ammonia gas, chlorine gas, chloramine)	Bleach, ammonia, detergents

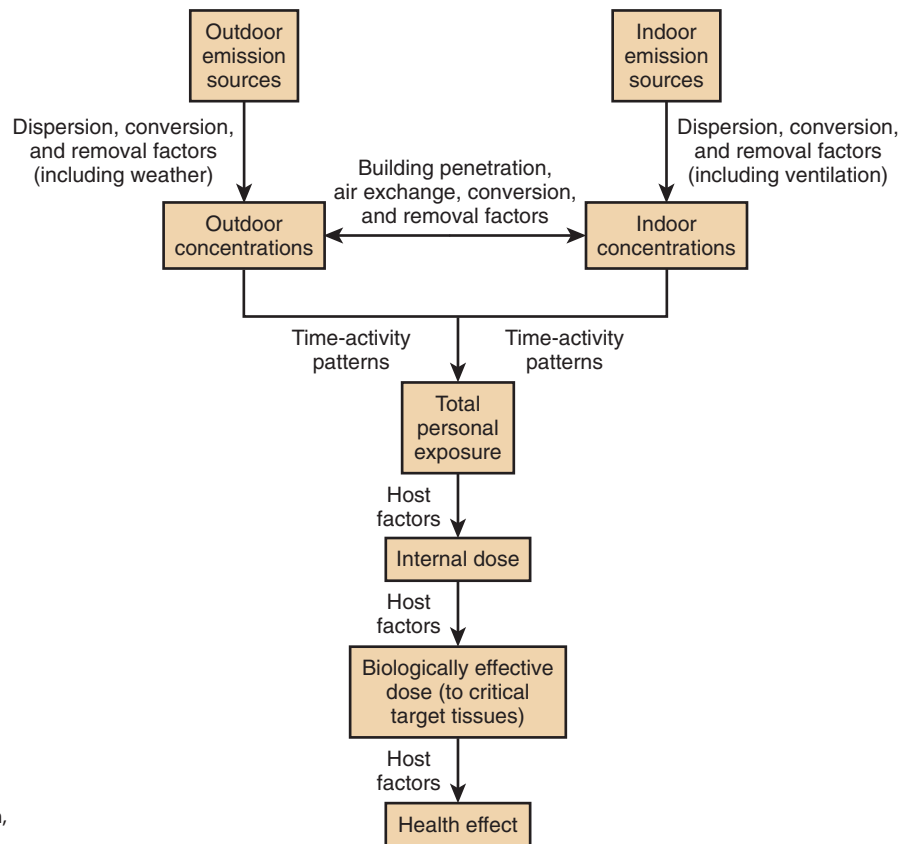

Figure 74-1 Relationships among outdoor pollution, indoor pollution, and health effects.

number of exterior walls and windows, surrounding terrain and barriers, wind speed and direction, indoor-outdoor temperature gradient, and ventilation system type (e.g., heating, ventilation, air-conditioning system) and efficiency.^{6,27,55}

Time-activity patterns will influence personal exposure. The relative time spent indoors versus outdoors will affect the contribution of indoor pollutants to total personal exposure. Time spent in specific locations within the home will affect exposure to particular pollutants, as the distribution of indoor pollutant concentrations will vary among different zones of a building, especially for pollutants generated indoors.⁵⁵ In addition, activity level will affect metabolic rate and ventilatory rate, which will also influence personal exposure to indoor pollutants.

INDOOR COMBUSTION: MAJOR SOURCE OF INDOOR AIR POLLUTION

The major source of indoor pollution is from combustion, particularly *secondhand smoke* (SHS) exposure, gas stove use, and wood burning in stoves and fireplaces. Kerosene space heaters are also an important source of indoor air pollution. Table 74-4 shows the major indoor pollutants that are released from these sources and are associated with adverse pulmonary effects.

SECONDHAND SMOKE AND OBSTRUCTIVE LUNG DISEASE

SHS is perhaps the best known and studied indoor pollutant. Strong evidence implicates it as a cause of lung cancer,

coronary heart disease, and decreased life span.⁵⁶⁻⁵⁸ In addition to these adverse health effects, SHS contains respiratory irritants, such as SO₂, ammonia, acrolein, and formaldehyde.⁵ SHS is a complex mixture containing thousands of gas-phase and particulate substances. Homes where smoking is allowed have PM_{2.5} levels up to 10 times higher than nonsmoking homes.⁵⁹ Workplace exposures can be even higher, especially in bars and casinos.

Passive smoking has also been linked with allergic phenomena, such as elevated serum immunoglobulin E levels.⁶⁰ As a consequence, SHS has the potential to induce new cases of asthma through irritant or sensitizing mechanisms. The results of multiple studies provide evidence that SHS exposure is causally associated with new-onset asthma among children.^{5,61,62}

Exposure to SHS also appears to be associated with new-onset asthma in adulthood. Cross-sectional, case-control, and cohort studies have suggested a link between SHS exposure and adult-onset asthma.⁶²⁻⁷⁰ SHS exposure in the workplace, in particular, appears to be related to adult asthma induction.⁶⁹

Beyond asthma induction, SHS exposure is a likely cause of asthma exacerbation in both children and adults.⁵ Parental smoking causes increased symptoms, poorer pulmonary function, and other indicators of worsened asthma control among children with established asthma.^{62,71} Similarly, SHS exposure, both at home and at work, appears to cause asthma exacerbation among adults.⁷²⁻⁷⁸ Moreover, the negative impact of SHS exposure on pulmonary function appears to be greater among adults with asthma than in the general population.^{72,79}

Exposure to SHS may also cause respiratory symptoms and impaired lung function among nonasthmatic individuals.^{67,72,80-82} In a cohort of older adults, lifetime home and workplace exposure to SHS was associated with a more rapid decline of lung function during a decade of follow-up.⁸³ Studies of bartenders who had high occupational exposures to SHS have revealed a strong link between SHS and poorer respiratory health. Since smoke-free workplace laws have been implemented in several different locations around the world, bartenders and restaurant workers have experienced a reduction of respiratory symptoms and improved lung function.^{79,84,85}

Emerging evidence now suggests that SHS exposure may also be a cause of COPD independent of personal cigarette smoking.^{85a} A population-based study from the United States found that both cumulative home and work SHS exposure was associated with a greater risk of COPD, controlling for potential confounders.⁸⁶ A recent study from China found that self-reported cumulative lifetime SHS exposure at home and work was related to a greater risk of COPD.⁸⁷ Other epidemiologic studies also support an association between SHS exposure and the development of COPD.^{67,88-92} Among patients with established COPD, SHS exposure may increase the risk of respiratory symptoms, poor health status, and disease exacerbations.⁹³⁻⁹⁵

GAS STOVE EXPOSURE: CAUSE OF ASTHMA EXACERBATION?

Cross-sectional epidemiologic studies demonstrate an increased risk of childhood asthma in homes with gas stoves, which are a major source of indoor NO₂, compared with homes with electric stoves,^{96,97} although a recent birth cohort study did not.⁹⁸ In adults with established asthma, a prospective panel study found an association between gas stove use and increased risk of respiratory symptoms, restricted activity, and emergency department visits.⁹⁹ Another time-series analysis found a negative impact of gas stove use on daily peak expiratory flow and respiratory symptoms.¹⁰⁰ In contrast, a longitudinal U.K. cohort study found no effect of gas stove exposure on persistence of adult asthma or on respiratory symptoms among asthmatics¹⁰¹; the European Community Respiratory Health Survey investigators found no clear link between gas stoves and asthma symptoms.¹⁰² Moreover, a prospective cohort study of adults with asthma found no impact of gas stove exposure on asthma outcomes^{77,103} and, in a population-based sample of U.S. adults, no association between gas stove exposure and pulmonary function impairment was observed.¹⁰⁴ Overall, the evidence has not been sufficient to implicate gas stove use as an exacerbating factor in preexisting adult asthma. Among children with asthma, however, there is stronger evidence of a deleterious effect of indoor NO₂ exposure and poorer asthma control.^{105,106}

WOOD SMOKE EXPOSURE—RESPIRATORY HEALTH EFFECTS

Wood smoke, which is produced from domestic fireplace or wood stove use, contains potent respiratory irritants such as formaldehyde, acrolein, nitrogen oxides, and SO₂. It is also a major source of particulate air pollution.¹⁰⁷ Exposure

to extremely high wood smoke levels has been linked with respiratory problems. After a work shift, forest firefighters experience an acute decrement in pulmonary function.¹⁰⁸ Similarly, wildland fires have been associated with increased respiratory symptoms and health care utilization for respiratory problems.¹⁰⁹ In developing countries, wood smoke from domestic cooking and heating in poorly ventilated homes has been associated with chronic bronchitis and COPD.^{6,94,110,111,111a} The exposure levels in such settings are extremely high and are likely the major cause of COPD in women in the developing world, who tend not to smoke cigarettes.¹¹⁰ Cooking with other biomass fuels, such as crop residues or dung, and with coal can also lead to chronic respiratory symptoms and airflow obstruction.¹¹¹ Cooking with wood and/or charcoal has been associated with risk of COPD in developed countries as well.

The respiratory health effects of residential biomass smoke exposure on asthma are not as clear. Previous studies have reported conflicting results.^{77,99,105,112-115} However, an analysis from the International Study of Asthma and Allergy in Children, which included more than 250,000 children from over 31 countries, did find an association between use of an open fire for cooking and prevalence of asthma symptoms and reported asthma.¹¹⁶ Exposures to wood smoke in developed countries are usually at much lower levels than in countries where a large proportion of the population cooks on open fires, so it is less clear how such exposures contribute to asthma burden.

RESPIRATORY EFFECTS OF KEROSENE HEATER USE

Kerosene heaters can substantially increase indoor levels of fine particles (PM_{2.5}), sulfate aerosol (SO₄²⁻), and acidic aerosol (H⁺), as well as CO.¹¹⁷ Kerosene is similar to diesel fuel in chemical composition. The existing evidence, however, is inconclusive about whether kerosene heater use is a cause of respiratory and asthma symptoms in developed countries.^{96,105,117-119} In developing countries where kerosene may also be used for lighting using inefficient wick lamps, this fuel has been associated with increased risk of respiratory infections, especially tuberculosis.^{120,121}

OTHER INDOOR POLLUTANTS—"TOXIC" INDOOR ENVIRONMENT

Besides indoor combustion, there are many other sources of indoor pollutants. Building materials, such as plywood or particle board, and carpeting can emit formaldehyde; furniture may release formaldehyde and *volatile organic compounds* (VOCs); paints, cleaning compounds, and photocopiers may release VOCs; and radon can arise from soil sources.^{6,27} Cleaning with bleach and other compounds can release chlorine and ammonia gas, which are airway irritants. Combination of bleach and ammonia or other nitrogen sources can also produce chloramine, which may induce upper and lower respiratory tract symptoms.¹²² Of these substances, radon exposure has been associated with lung cancer.¹²³ Exposure to chlorine, chloramine, and VOCs may be linked with respiratory symptoms, some of which suggest asthma, but further evidence is necessary before final conclusions can be drawn.^{122,124,125}

OUTDOOR AIR POLLUTION— ADVERSE RESPIRATORY EFFECTS OF SPECIFIC POLLUTANTS

PARTICULATE MATTER

Since the catastrophic air pollution events of the Meuse Valley, Donora, and the London Fog, hundreds of epidemiologic studies have examined the health impacts of particulate air pollution. There is strong and consistent evidence that particulate pollution causes premature death, which is principally from cardiovascular and respiratory causes.^{22,26,126-130} Both short-term exposure, measured as daily fluctuation of particulate pollutant levels, and longer-term chronic exposures have been linked with mortality. In particular, the Harvard Six Cities Study and the American Cancer Society study have provided key insights into the long-term health impacts of particulate air pollution. Evidence linking PM₁₀ and PM_{2.5} to mortality is robust but particularly strong for PM_{2.5}. Although particulate pollution is strongly correlated with other pollutants, such as SO₂, PM has a strong independent effect on mortality.

PM increases respiratory symptoms. For example, exposure to PM has been associated with lower respiratory tract symptoms among children, such as cough, wheezing, or shortness of breath.¹³¹⁻¹³³ Children with asthma are especially vulnerable.^{134,135-138} Adults with asthma who are exposed to higher levels of PM have an increased risk of health care utilization for exacerbations.^{139,140}

PM is also associated with poorer lung function, both in children and in adults. The Children's Health Study conducted in Southern California, which followed thousands of children over many years, found that fine particulate pollution was linked to a reduced rate of lung function growth.¹⁴¹⁻¹⁴³ Another study used carbon content of airway macrophages as a biomarker of individual exposure to PM derived from fossil fuel; there was a dose-dependent inverse association between the carbon content of airway macrophages and lung function, including *forced expiratory volume in 1 second* (FEV₁), in children.³⁰ Because it used an airway-related biomarker of particulate exposure, this study provides key support for the connection between particulate exposure and impaired lung function in children. In adults, particulate pollution has also been linked to poorer lung function and increased risk of COPD, which may reflect decreased growth of lung function in childhood or accelerated decline subsequently.^{94,141,144,145} In support of a link between particulate pollution and COPD, other studies have linked ambient particle exposure to a greater risk of hospitalization and death from COPD.^{139,140,146-148}

Importantly, a reduction in particulate air pollution translates to improved pulmonary function and a longer life span for the population. A Swiss study (SAPALDIA) examined the association between the 11-year change in air quality and lung function decline among a large sample of adults.¹⁴⁹ A PM₁₀ reduction of 10 µg/m³ was associated with a decreased rate of annual decline of FEV₁. To address the impact of declining PM_{2.5} levels on mortality, another study examined 211 metropolitan counties throughout the United States from approximately 1980 to 2000.¹²⁸ A decrease in PM_{2.5} of 10 µg/m³ was associated with a mean

increase in life expectancy of 0.61 years, after taking into account measures of sociodemographic and smoking factors. During the 2 decades of the study, the average life expectancy increased 2.72 years. The authors estimated that up to 15% of this improvement in life span could be attributed to declining particulate pollution levels. In the Harvard Six Cities Study, declining fine particle levels were also shown to be associated with reduced mortality in the United States.¹²⁶

Another important component of particulate pollution is diesel exhaust. Diesel exhaust from heavy-duty trucks and diesel-engine cars is a major contributor to particulate air pollution in many parts of the world. Diesel exhaust particles have a central carbon core and adsorbed organic compounds, including *polycyclic aromatic hydrocarbons* (PAHs) and other known carcinogens. Occupational exposure to diesel exhaust among truck drivers, railroad workers, and miners has been associated with an elevated risk of lung cancer.¹⁸⁻²¹ Toxicologic studies have confirmed the carcinogenic properties of diesel exhaust.²¹

Diesel exhaust exposure can cause acute deterioration of lung function among persons with asthma. A randomized crossover study randomly assigned adult subjects with mild to moderate asthma to walk along Oxford Street in London at lunchtime (the busiest shopping street, in which only diesel powered buses and taxis are allowed) or in Hyde Park.¹⁵⁰ Fine and ultrafine particle levels were approximately three times higher on Oxford Street than in Hyde Park. The maximal decline in FEV₁ was much greater for subjects walking on Oxford Street than in Hyde Park, and sputum biomarkers of neutrophilic inflammation were also increased after the street walks. Other studies indicate that diesel exhaust may favor a Th2 immune response, further connecting this form of particulate pollution with allergic disease and asthma.^{151,152} Diesel exhaust contains PAHs that have been shown to worsen asthma outcomes, potentially through an epigenetic mechanism to decrease T regulatory cell function.¹⁵³

SULFUR DIOXIDE

The major source of sulfur oxides in the ambient environment is the combustion of sulfur-containing fossil fuels such as coal and crude petroleum. SO₂ is the most important of the gas-phase *sulfur oxides* (SO_x) in terms of both atmospheric chemistry and health effects. Sulfur oxides are usually considered to include *sulfur trioxide* (SO₃) and gas-phase *sulfuric acid* (H₂SO₄), but neither is present in the atmosphere in concentrations that result in substantial human exposures except when there are industrial or transportation accidents. Sulfur dioxide is regulated by the EPA as a criteria pollutant. A newly recognized source of exposure to SO₂ that has been associated with acute health effects is volcanic emissions.¹⁵⁴

Bronchoconstriction is the primary acute effect of SO₂ and is likely mediated by chemosensitive receptors in the tracheobronchial tree. In particular, persons with asthma are most sensitive to the effects of SO₂, which may result from preexisting airway inflammation that leads to enhanced release of mediators, alterations in the autonomic nervous system, and exaggerated response of the chemosensitive receptors.^{155,156} Multiple controlled human

exposure studies have observed symptomatic bronchoconstriction in exercising asthmatics following 5- to 10-minute exposures to SO₂ at concentrations that are similar to those found in ambient air.^{157,158} In the published studies, 5% to 30% of relatively healthy asthmatic subjects experienced moderate or greater decrements in lung function (>100% increase in specific airway resistance or >15% decrease in FEV₁) with exposures to SO₂ concentrations of 200 to 300 ppb during exercise (compared with the current EPA standard of 75 ppb over a 1-hour averaging time).^{32,158} At concentrations of 400 ppb or greater, a greater percentage (20% to 60%) of exercising asthmatic individuals experienced SO₂-induced bronchoconstriction. A clear concentration-response relationship has been demonstrated following exposures to SO₂ at concentrations between 200 and 1000 ppb, in terms of both increasing severity of effect and proportion of asthmatic individuals affected. Individuals without asthma do not typically experience bronchoconstriction at these levels.

The results of multiple epidemiologic studies show associations between short-term exposures (generally 24-hour averages) to ambient SO₂ and respiratory morbidity. These studies were conducted in areas where the mean ambient 24-hour average SO₂ concentration ranged from 1 to 30 ppb, with maximum values ranging from 12 to 75 ppb. Several multicity studies and single-city studies have found an association between 24-hour average SO₂ concentrations and respiratory symptoms in children, particularly those with asthma.¹⁵⁹⁻¹⁶² Generally consistent associations have also been observed between ambient SO₂ concentrations and lung function decrements and health care utilization for all respiratory causes, particularly among children and older adults (≥65 years), and for asthma.¹⁶³⁻¹⁶⁷

The observed associations of asthma symptoms and lung function changes with 24-hour average SO₂ exposures in epidemiologic studies may be due to short-term peak exposures similar to the 5- to 10-minute exposures that have produced symptomatic bronchoconstriction in controlled human exposure studies. In other words, the effects of SO₂ on respiratory symptoms and lung function observed in human experimental studies using peak exposures are coherent with the increased emergency department visits and hospital admissions observed in epidemiologic studies. To protect asthmatic individuals from acute episodes of bronchoconstriction, in 2010 the EPA added a 1-hour ambient air quality standard for SO₂ of 75 ppb.

Because SO₂ and PM_{2.5} are both emitted from the combustion of sulfur-containing fuels such as coal and heating oil, epidemiologic studies of SO₂ need to address potential confounding by this and other co-pollutants. In studies that have evaluated multipollutant models, the effect of SO₂ on respiratory health outcomes appears to be robust and independent of the effects of gaseous co-pollutants, including NO₂ and O₃, but the effect of SO₂ is not always found to be independent of PM.^{165,168}

Several studies have assessed the effects of decreases in SO₂ concentrations on respiratory symptoms due to air quality regulations. In eastern Germany, a marked decline in ambient SO₂ concentrations (90% across the decade of the 1990s) was associated with a decrease in the prevalence of respiratory symptoms.¹⁶⁹ During the study period, however, concentrations of other ambient air pollutants

also decreased, including that of PM, which was approximately 60% lower. In a similar study of the effect of a 1990 regulation requiring use of low-sulfur fuel for power generation and on-road vehicles in Hong Kong, large reductions in ambient SO₂ concentrations of up to 80% were associated with reduced respiratory symptoms; in this study, reductions in ambient PM were less than 20%.¹⁷⁰ Although the improved respiratory symptoms observed in both of these intervention studies may be partially attributable to declining concentrations of air pollutants other than SO₂, the results nevertheless provide support for a causal relationship between SO₂ and respiratory health.

NITROGEN DIOXIDE

The term *oxides of nitrogen* (NO_x) includes all forms of oxidized nitrogen compounds, including *nitric oxide* (NO), *nitrogen dioxide* (NO₂), and all other oxidized nitrogen-containing compounds formed from NO and NO₂. NO_x is emitted by combustion sources mainly as NO with smaller quantities of NO₂. Motor vehicles and electric utilities are the two largest NO_x sources in the United States. NO is the primary NO_x species emitted from most combustion sources but is rapidly converted to NO₂; thus, NO₂ is the focus of most health effects studies. NO₂ is another of the criteria pollutants regulated by the EPA to protect public health. It is an oxidant gas like O₃ but less potent. Although high concentrations sometimes found in silos are well known to cause the acute and sometimes lethal pulmonary edema of “silo filler’s disease,”¹⁷¹ the much lower levels of NO₂ in outdoor air had not been definitively linked to adverse health effects in epidemiologic studies until the past decade. When it became apparent that indoor concentrations of NO₂ often exceeded outdoor concentrations, particularly in homes equipped with gas stoves, research interest focused on the possibility that exposure to NO₂ in indoor air might increase the frequency of respiratory infections, in part because of animal studies showing that exposure increased risk of infection.¹⁷²

Controlled human exposure studies provide evidence for increased airway responsiveness to both nonspecific and specific challenges in asthmatic subjects after short-term exposure to NO₂. The results of several older studies suggested that short-term (30- to 60-minute) exposures to NO₂ at concentrations in the range of 100 to 300 ppb may cause increased airway responsiveness to nonspecific bronchoconstrictor agents such as methacholine and histamine.¹⁷³ More recent studies involving allergen challenge in asthmatics suggest that NO₂ may enhance both allergen-induced bronchoconstriction and inflammatory responses after exposures as low as 260 ppb NO₂ for 30 minutes during rest.^{174,175}

Evidence from a number of epidemiologic studies supports an association between ambient NO₂ and respiratory morbidity, especially among persons with asthma. In particular, a study that evaluated the effect of an intervention that reduced indoor exposure to NO₂ from gas heaters provided evidence of improvement in respiratory symptoms in asthmatic children.¹⁷⁶ Studies using community ambient monitors to assign exposures to NO₂ also found associations between ambient NO₂ and respiratory symptoms in asthmatic children.^{10,159} Positive associations were observed in

cities where the 24-hour average ambient concentrations were within the range of typical large U.S. urban areas. The results of multipollutant models generally showed that the NO₂ associations were robust after adjustment for co-pollutants including O₃, PM, and CO.

Multiple epidemiologic studies have shown positive associations between short-term ambient NO₂ concentrations and emergency department visits and hospital admissions for respiratory causes, especially asthma.^{168,177-179} These associations are particularly consistent for children and older adults (age 65+ years) when considering all respiratory diseases as the outcome and, for children and adults of all ages when considering asthma as the outcome.

In addition to the epidemiologic evidence that short-term exposure to ambient NO₂ can cause respiratory morbidity, long-term exposure to NO₂ has been associated with decreased rate of growth of lung function. Results from the longitudinal Children's Health Study indicated that decrements in lung function growth were substantial for boys and girls who lived in southern California communities with relatively high annual average ambient NO₂.¹⁴¹ The mean annual NO₂ concentrations in the communities ranged from approximately 5 to 40 ppb, well below the current EPA national ambient air quality standard of 53 ppb as an annual average. Similar associations have also been found for PM, inorganic (mostly nitric) acid vapor, and proximity to traffic (<500 m) in this cohort; the high correlation among traffic-related pollutants makes it difficult to determine the independent effect of NO₂ on lung function growth.^{141,180}

Of interest, the results of several studies, including two from the Children's Health Study, suggest that long-term residential exposure to NO₂ is associated with increased risk of developing asthma in children.^{181-183,183a} However, it may be that NO₂ itself is not the causal agent, but rather that NO₂ concentrations are a good marker of exposure to the traffic pollution mixture.¹⁸²

Because short-term exposures to NO₂ can induce greater airway responsiveness among asthmatic subjects in human experimental studies and are associated with respiratory outcomes, especially asthma, in epidemiologic studies, there is coherent evidence to support a short-term averaging time for air quality standards to control this pollutant. To protect individuals with asthma from acute exacerbations, the EPA promulgated a new 1-hour ambient air quality standard for NO₂ of 100 ppb in 2010.

OZONE

O₃ is a colorless, pungent, relatively water-insoluble gas that, together with other photochemical oxidants and fine particles, forms "smog." Tropospheric, or ground-level, O₃ is an environmental air pollutant and is distinct from the stratospheric O₃ found at altitudes of greater than 10 km (6.2 miles) above the earth's surface. O₃ is generated by a series of sunlight-driven reactions involving NO_x and VOCs from predominantly mobile (i.e., motor vehicle) but sometimes stationary sources. The meteorologic conditions that tend to foster the generation of O₃ are typically present from late spring to early fall. O₃ reaches peak concentrations typically in mid-afternoon, after both the morning rush hour and several hours of bright sunlight. Because of its high

chemical reactivity, ambient O₃ tends not to penetrate well into buildings. However, indoor sources of O₃ include office equipment with electric motors or ultraviolet light, such as photocopy machines, and electrostatic devices, such as air purifiers and ion generators.

Although O₃ has long been associated with southern California smog, many other areas of North America also experience high concentrations of this pollutant, especially Houston, Mexico City, and cities in the eastern United States and Canada during the summer months. In these areas, there are many days each year when the current EPA national ambient air quality standard for O₃ is exceeded.

Ozone is a potent oxidant and is capable of reacting with a variety of extracellular and intracellular molecules. When ozone reacts with unsaturated lipids, free radicals and toxic intermediate products that can lead to cellular damage or cell death are generated.¹⁸⁴ Direct cytotoxicity is a major mechanism of O₃-induced tissue injury; secondary damage from the inflammatory response likely also plays a role.

Dosimetric studies indicate that much of the inhaled O₃ is deposited in the upper and proximal lower airways.¹⁸⁵ However, because of its relative water insolubility, a considerable fraction will penetrate to the distal airways and alveoli. At the tissue level, the dose is highest at these sites.¹⁸⁶ Increased inspiratory flow, as would be seen with exercise, may overwhelm the upper airway "scrubbing mechanisms" and cause greater deposition of O₃ in the distal lung.¹⁸⁷

Most of the research on the health effects of O₃ has focused on short-term exposure. In controlled human exposure studies, O₃ inhalation by healthy subjects causes decrements in FEV₁ and FVC that correlate with concentration, exposure duration, and minute ventilation.¹⁸⁸⁻¹⁹⁰ These decrements in lung function are primarily a result of decreased inspiratory capacity rather than airway obstruction. The mechanism of the decreased inspiratory capacity appears to be neurally mediated involuntary inhibition of inspiratory effort involving stimulation of C fibers in the lungs.¹⁹¹ Somewhat surprisingly, older subjects and those who are cigarette smokers demonstrate lower O₃-induced decrements in pulmonary function than younger, healthy subjects.¹⁹² The acute decrements in pulmonary function induced by O₃ usually resolve within 24 hours. Statistically significant decrements in FEV₁ have been demonstrated in healthy subjects with exposures during exercise to concentrations below the current U.S. air quality standard.¹⁹³

Respiratory symptoms (e.g., substernal chest discomfort, cough, wheeze, dyspnea) are correlated with these decrements in pulmonary function.¹⁹⁰ Another adverse effect of short-term exposure to O₃ is enhanced airway responsiveness to nonspecific stimuli such as methacholine and histamine.¹⁹⁰ This effect may persist longer than the acute decrements in lung function and may be seen even in individuals who do not experience a decline in their FEV₁.

Ozone exposure may induce adverse respiratory consequences through a variety of mechanisms. These include nasal inflammatory changes, injury to type I alveolar cells, ciliated airway epithelial cell injury, infiltration of the airway mucosa by neutrophils, and increased bronchoalveolar lavage fluid neutrophils and inflammatory mediators.¹⁹⁴⁻¹⁹⁶

Airway inflammation has been demonstrated after exposure to ambient concentrations with exercise, including levels below the current U.S. air quality standard.^{193,197}

The effects of chronic O₃ exposure in humans have not been adequately defined. It has been hypothesized that chronic exposure would lead to structural changes; however, to date, most toxicologic studies involving rodents have failed to demonstrate structural damage after long-term exposure to ambient concentrations. However, studies with rhesus monkeys have shown that O₃ exposure of neonatal rhesus monkeys led to abnormal development of conducting airways, especially with coexposure to house dust mites.¹⁹⁸ In addition, some epidemiologic studies, but not all, suggest that long-term residence of children in a high ambient O₃ environment can lead to remodeling of the small airways.^{141,199,200}

Multiple epidemiologic studies show that high ambient O₃ concentrations are associated with an increased rate of asthma attacks and increased respiratory-related hospital admissions/emergency department visits for respiratory disease.^{201,202} The biologic plausibility of these findings is supported by the results of controlled human exposure studies showing that O₃ increases nonspecific airway responsiveness, asthmatic subjects have a greater inflammatory response to exposure, and specifically sensitized asthmatic subjects have enhanced bronchoconstrictor responses to inhaled allergen.^{203,204} In addition to the exacerbation of preexisting asthma, some evidence exists that exposure to O₃ could induce new cases of asthma; for example, children playing outdoor sports in polluted areas of the Los Angeles basin have a threefold to fourfold increased risk of asthma.²⁰⁵

Both short-term and long-term exposures to O₃ have been associated with increased risk of mortality; this has been reported in both Europe and the United States.²⁰⁶⁻²⁰⁸ Although this effect was first reported for respirable PM, both O₃ and fine PM are capable of generating oxidative stress and local inflammation deep in the lung. Similar to what has been observed in PM mortality studies, it appears that elderly people with preexisting heart and lung disease represent the group at greatest risk for O₃-related death. If excess oxidative stress is a critical step in a pathway that leads to early mortality in individuals with heart and lung disease, it is not surprising that exposure to both ambient O₃ and PM is associated with increased risk. Of additional concern, several studies have suggested that young adults living in southern California have increased oxidative stress and cytogenetic damage compared with those living in northern California, perhaps related to differential exposure to O₃.^{209,210}

In summary, tens of millions of persons in the United States are exposed to levels of O₃ above the current U.S. national ambient air quality standard. This exposure is capable of inducing both acute decrements in lung function and respiratory symptoms. Although these effects are transient, acute respiratory tract injury and inflammation can also be induced by short-term exposure to ambient concentrations of O₃. Exacerbations of asthma and increased risk of death of the elderly appear to be the most important health effects of short-term exposure. The long-term consequences of O₃-induced acute injury and inflammation are not well understood, but there is epidemiologic evidence consistent with airway remodeling.

Key Points

- Although the hazard of air pollution for human health has been recognized for less than a century, great progress has been made in defining the sources, properties, and distribution of pollutants. More recently, the importance of indoor air pollution has become clear.
- Epidemiologic studies, taken together with controlled human exposure studies, animal studies, and in vitro studies, have delineated many of the serious respiratory and cardiovascular health effects of air pollution. Significant questions remain, however, about the impact of multiple pollutants acting together, the effect of pollution on susceptible populations, and the minimum ambient levels at which the risk of health effects increases. Further research is needed to answer these important questions.
- Great progress has been made in clearing the air in the United States and other developed countries, but levels of indoor and outdoor pollutants remain higher than is desirable for human health. In developing countries, a major source of air pollution is biomass smoke from domestic heating and cooking, which may be the world's leading cause of obstructive lung disease among women.
- Further research that addresses the important remaining questions in air pollution, especially the question of what are safe thresholds for air pollutants of concern, including biomass smoke, will inform future policy efforts to protect public health.

Smoke Inhalation

Pharmacologic Syndromes

Other Inhalant Exposures

Miscellaneous Exposures

INTRODUCTION

This chapter focuses on the acute effects on the lung after exposure to toxic substances. As used in this chapter, *acute* indicates short-term exposures (minutes to hours), with the initial onset of pulmonary responses within a similarly rapid time period. Generally, the relevant toxicant exposures are of high intensity, far in excess of recommended safety limits for population-wide environmental levels or even workplace-permissible limits. In this chapter, the *target organ* discussed for the toxicants is the lung. Importantly, *target organ* does not equate with *route of exposure*. For most acute exposures, inhalation is the route of delivery leading to the lung injury. Because ingestion may also lead to lung injury, paraquat and hydrocarbon, examples of ingested toxins with severe acute target organ effects on the lung, are included in this chapter. However, in some instances, inhalation may be the route of delivery for the toxicant and yet the primary target organ is not the lung (e.g., solvent inhalation that causes central nervous system depression). Inhalation exposures leading to nonpulmonary illnesses are not addressed here.

Moreover, this chapter does not address brief exposures inducing acute responses mediated by anamnestic (i.e., allergic or other immune-mediated) mechanisms. These responses require prior exposures that have already led to sensitization, such as hypersensitivity pneumonitis (see Chapter 64) or occupational asthma (see Chapter 72). There are also a number of toxicants causing unusual pulmonary syndromes after subacute (days to months) as opposed to acute exposure. Some of these syndromes have emerged in recent years associated with new technologies or novel toxicants, such as diacetyl-caused popcorn worker's lung and other flavor industry workers' diseases linked to this chemical,^{1,2} "flock workers' lung" caused by short synthetic textile fibers,^{3,4} and "Ardystil lung," a dye chemical-induced organizing pneumonia.^{5,6} Although beyond the scope of this chapter, some of these syndromes are discussed elsewhere.

PATHOGENESIS OF LUNG INJURY FROM INHALED TOXICANTS

PATTERNS OF RESPONSE TO IRRITANT INHALATION

Acute lung toxicity results from a variety of exposures but, nonetheless, is manifest by a narrow repertoire of injury (Table 75-1). Irritant toxic substances can be encountered in various physical states relevant to their inhalational properties. Such states include *gases*, *vapors* (i.e., the gaseous form of a substance that is a liquid or a solid at normal temperatures and pressures), and *fumes* (i.e., solid material, often metals, of small particle size suspended in a gaseous medium (most < 1.0 μm and many < 0.1 μm). *Aerosols* encompasses a mix of potential states (i.e., liquid droplets or fine particulates dispersed in a gaseous medium; *smoke* is a subset of aerosol resulting from incomplete combustion).

These various classes of exposures include heterogeneous toxic agents that are capable of causing extensive cell injury throughout the upper and lower respiratory tract. The primary location of respiratory tract injury and the onset of clinical symptoms are partly dependent on the solubility of the gas, vapor, fume, or aerosol involved and, in the case of fumes or aerosols, particle or droplet physical characteristics. Other factors that determine the injury pattern following exposure include (1) amount of the toxic substance inhaled, (2) duration of exposure to the inhalant, (3) concentration of the inhalant in the ambient air, (4) other physical properties (such as pH or chemical reactivity), and (5) a variety of host factors, such as age, use of respiratory protection, and comorbid illness. Overwhelming exposures to any irritant inhalant, however, can cause extensive damage throughout the respiratory tract.

Ammonia⁷ and sulfur dioxide⁸ are examples of substances that are highly soluble in water. Such highly soluble substances cause immediate irritation of the conjunctival mucosa and upper airways. In contrast, oxides of nitrogen,⁹

Table 75-1 Major Clinical Scenarios of Pulmonary Responses Shortly After Acute Toxicant Exposure

Clinical Scenario	Exemplar Exposures	Additional Comments
Mucous membrane and airway irritation (burning eyes, nose, and throat; laryngospasm and bronchospasm) with or without lower lung injury (pulmonary edema, diffuse alveolar damage)	Chlorine, chlorine dioxide, chloramine; bromine; sulfur dioxide; acid aerosols (sulfuric, hydrochloric, hydrofluoric); ammonia; zinc chloride (smoke bombs)	At low exposures, mucous membrane irritation may be the sole effect; with heavy exposure, lower lung injury may be seen.
Lower lung injury (pulmonary edema, diffuse alveolar damage) with little or no mucous membrane irritation or airway effects	Nitrogen dioxide, phosgene, ozone, cadmium fume, mercury vapor, nickel carbonyl, fluorocarbon (waterproofing)	Exposure can be inadvertent or occult with presentation delayed 24–48 hr
Self-limited flulike illness with fever and leukocytosis beginning 6–12 hr after a clear exposure history	Zinc oxide fume, heavy organic dust inhalation, polymer fume, endotoxin	The presence of hypoxemia or lung injury indicates another diagnosis
Foreign substance ingestion followed by pneumonitis	Hydrocarbon aspiration, exogenous lipid pneumonia, paraquat fibrosis	Heavy aerosol inhalation can cause lipid pneumonia; paraquat can also be absorbed through the skin

ozone,¹⁰ and phosgene¹¹ have relatively low water solubility. For this reason, exposure to one of these agents may *not* be characterized by immediate symptoms of mucous membrane irritation. This may lead to more prolonged exposure and delay in seeking medical attention. Both more and less soluble irritant exposures can lead to distal lung injury, but in the case of highly soluble materials, a history of severe upper respiratory symptoms should precede the presentation of distal airway and alveolar damage.¹²

Irritants reaching the lower respiratory tract, either because of their inherent physical characteristics or because of exposures that overwhelm the absorptive capacity of the upper airway, can injure both the lung epithelium and its endothelium. Pathophysiologically, irritant injury at this level leads to a nonspecific pattern of diffuse alveolar damage similar to that seen from a variety of different causes (see Chapter 15). The pathologic changes in fatal cases of irritant lung injury include focal and confluent areas of edema with protein-rich fluid in the alveolar spaces, hyaline membrane formation, and denudation of the alveolar epithelium. In addition, mucous membranes of the bronchial and bronchiolar walls may be destroyed or denuded. Some pulmonary hemorrhage may be seen in irritant lung injury but is typically not the dominant clinical-pathologic manifestation; prominent pulmonary hemorrhage should raise suspicion of other toxicant- or nontoxicant-mediated syndromes¹³ (see Chapter 67).

On the cellular level, respiratory tract injury may be mediated through the deposition or formation of an acid, alkali, free radical, or other reactive chemical species. The precise cellular mechanisms of injury from irritant inhalants have not been fully delineated even for relatively common irritants such as chlorine or even the chemical warfare agent phosgene, substances for which a great deal of human and experimental animal data exist.^{14–17}

OTHER PATTERNS OF RESPONSE

Acute irritant inhalation injury is the predominant, but not the only, pathophysiologic mechanism underlying acute toxic lung syndromes. In contrast to the anatomic distribution commonly seen in water-soluble, irritant chemical-related inhalant injury, it may be difficult to delineate a descending, hierarchical pattern from upper airway to lower lung injury following exposure to a diverse group of

other agents. Many of these exposures, as with the water-soluble irritants, also lead to acute lung injury via nonimmunologic mechanisms (clinically, acute respiratory distress syndrome; pathologically, diffuse alveolar damage), as detailed subsequently in this chapter. Other toxicant exposures produce various other syndromes of respiratory tract injury, such as heavy metal pneumonitis,¹⁸ hydrocarbon aspiration,¹⁹ or paraquat lung injury.^{20,21} The inhalation fever syndromes are an exception in that they do not involve obvious lung injury; the pathophysiology of this group of self-limited acute lung syndromes appears to be cytokine-mediated.²²

GENERAL MANAGEMENT PRINCIPLES

Symptoms and signs of acute inhalation injury can be delayed in onset. Following removal from exposure while safeguarding the rescuing personnel, the next most important management decisions include protection of the airway (i.e., preemptive intubation may be required to prevent precipitous airway obstruction from progressive airway edema) and treatment of hypoxemia. The nasopharynx and larynx may manifest injuries earliest because they are exposed to the highest concentrations of inhaled water-soluble toxicants. The upper airway may also be a primary target organ due to angioedema in selected toxicant ingestions.²³ Within a few hours after exposure, progressive airway edema, mucopurulent sputum production, and bronchorrhea may develop. Bronchoconstriction, peribronchial edema, and bronchial mucosal sloughing may produce atelectasis. In the distal airways and alveoli, epithelial and endothelial injury leads to permeability-induced edema, which can manifest ranging from mild interstitial edema to diffuse alveolar damage. Pulmonary edema may be rapid following high-concentration toxicant exposure or delayed up to 24 to 48 hours. Pneumothorax and pneumomediastinum can be acute complications of respiratory tract injury due to chemical toxicants.^{24–29} Diffuse alveolar damage after severe acute toxic lung injury should be managed consistent with the basic management of acute lung injury due to other causes. This extends to the role of protective ventilation strategies.³⁰ Concomitant airway injury with acute

bronchospasm often warrants treatment with bronchodilators because of the airway obstruction.

A beneficial role for systemic corticosteroids in the acute phase of irritant and other chemically mediated forms of acute injury to the lungs has not been established, by either controlled trials in humans or studies using experimental animal models.^{31,32} Inhaled steroids are more likely to have a better risk-benefit ratio in the therapy of acute inhalation injury (e.g., in the context of bronchospasm and concomitant use of bronchodilators, taking acute smoke inhalation injury as a paradigm).³³ Despite the lack of controlled evidence of efficacy, anecdotal reports of benefits from systemic corticosteroid use continue to appear.²⁸ Prophylactic antibiotic drugs have not proved to be efficacious in toxic lung injury; antibiotics should be reserved for those patients with clinical evidence of infection, including ventilator-associated pneumonia.^{34,35} To date, convincing data do not support the use of other pharmacologic agents, such as antioxidants, in the generic treatment of toxic chemical lung injury, although this is the subject of active experimental research.^{31,36}

There are certain exposure-specific management issues that do occasionally arise. In paraquat-induced lung injury, for example, oxygen toxicity is a particular concern because of the specific mechanism of action of paraquat (i.e., high concentrations of oxygen may lead to more severe lung injury).²⁰ In paraquat as well, immunosuppressive therapy has been of particular interest and has yielded some promising data but remains to be confirmed in randomized, controlled studies.²¹ In the case of certain metal toxins, chelation may have a therapeutic role, as is addressed later in relation to the specific exposures involved. Inhalation fever is self-limited, so the principal clinical management issue is to exclude other exposures with more serious outcomes.²²

CHRONIC SEQUELAE AND RESIDUAL EFFECTS

Among persons surviving symptomatic exposure to acute irritants, there may be persistent structural and functional effects. Long-term consequences to the upper airways (nose, pharynx, and larynx) can be sequelae of acute inhalational exposures; upper airway complaints including chronic rhinitis (*reactive upper airway dysfunction syndrome* [RUDS]), anosmia, and vocal cord dysfunction have been reported.³⁷⁻⁴⁰

Follow-up studies of more homogeneous populations evaluated after inhalation injury (with only a minority experiencing severe injury) suggest that airflow obstruction and nonspecific airway hyperresponsiveness are the most common persistent abnormalities of the conducting airways after irritant injury. Even so, epidemiologic data suggest that only a minority of those exposed will experience these outcomes.⁴¹⁻⁴³ The term *reactive airway dysfunction syndrome* (RADS) has been applied to the persistence of airway reactivity after acute exposure to respiratory irritants.⁴⁴⁻⁴⁷ The more general term *irritant-induced asthma* has also been used to describe this condition.^{48,49} Insofar as this syndrome represents a form of work-related asthma, it is addressed in Chapter 72.

Chronic injury to the lower airways and lung parenchyma are unusual sequelae of acute inhalational exposure. Long-term follow-up evaluation after recovery from acute respiratory distress syndrome due to heterogeneous causes (predominantly associated with sepsis) suggests that residual deficits in lung volumes, airflow, and gas exchange may persist long after recovery.⁵⁰ *Bronchiolitis obliterans* (BO),⁵¹⁻⁵⁸ bronchiectasis,^{7,57,59-62} and organizing pneumonia^{63,64} may all develop but are rare complications. Irritants, in particular nitrogen oxide and related exposures, have long been known to cause BO.⁶⁵ Yet even with nitrogen dioxide, BO is an infrequent event; for example, only 1 case was found in a series of 20 moderate to severe exposures.⁵² Pathologically, irritant-induced BO is usually characterized by intrabronchial granulation tissue (to which the term *proliferative bronchiolitis obliterans* is sometimes applied), as opposed to constrictive (obliterative) BO. The latter appears to be the pathologic correlate of diacetyl-caused popcorn worker's lung² and has been reported in one case of BO following exposure in the World Trade Center disaster,⁶⁶ in a case series of Iraq and Afghanistan military veterans (although no single toxic exposure has been implicated),⁶⁷ and in association with styrene-fiberglass boat construction, presumably with indolent rather than acute exposure.⁶⁸ In addition to residual obstructive ventilatory deficits, restrictive deficits may also result from severe irritant inhalation injury.^{59,69} There is also some indication that an isolated reduction in residual volume may be noted in the follow-up of such cases.^{70,71} Finally, nonspecific respiratory complaints after acute inhalation events can be a somatic manifestation of psychological processes and can be further complicated by *posttraumatic stress disorder* (PTSD) comorbidity.⁷²⁻⁷⁵

SPECIFIC EXPOSURES (Table 75-2)

CHLORINE, CHLORAMINES, HYDROCHLORIC ACID, AND RELATED CHEMICALS

Among the toxic agents causing pulmonary responses, *chlorine* is a common and potent irritant inhalant accounting for substantial human morbidity.^{15,76,77} Common forms of exposure include industrial leaks,^{78,79} environmental releases primarily during transport,^{80,81} water purification,⁸² swimming pool-related events,^{83,84} household cleaning product misadventures,⁸⁵ and even homemade chemical bombs⁸⁶ or intentional terrorist use.⁸⁷ In the form of a yellow-green acrid gas, industrial and environmental releases typically present clear-cut exposure histories. Because the gas is heavier than air, higher contamination can be expected in low-lying areas (hence, its use in trench warfare in World War I).⁸⁸ However, other environmental conditions may supervene. Examples include one well-documented case of the gas rising along the heated outside wall of a factory where rooftop workers were exposed.⁷⁸ In another case, chlorine initially collected in a basement but then was sucked up into the central heating system of a dormitory.⁸⁹

The history of exposure to chlorine may be less straightforward when the chlorine is generated after *de novo* generation from chlorine-containing products. Chlorine gas

Table 75-2 Selected Toxic Agents Causing Pulmonary Responses After Acute Exposure

Agent	Common Exposure Scenarios	References
Acid aerosols	Plating; microelectronics; other manufacturing	110, 125–129
Acrolein	Structural or wildland fires; other combustion	269, 270
Ammonia	Industrial refrigeration leaks; fertilizers	7, 294, 298
Brevetoxin	Aerosolization of “red tide” toxin	285, 287
Bromine	Water treatment; chemical manufacturing	58, 299–302
Cadmium fume	Flame cutting of soldered or sheet metal materials	168–172
Chloramines and nitrogen trichloride	Bleach + ammonia mix; chlorination + ammonia	90–92
Chlorine gas	Gas leak; water treatment; bleach + acid mix	14, 76–85
Chlorine dioxide	Pulp paper bleaching	116, 117
Crowd control agents (tear gas)	Military and police training and operations	157–160
Dimethyl sulfate	Industrial chemical yielding sulfuric acid	123, 124
Fluorocarbon polymers	Overheating polymers	131, 198, 204
Fluorocarbon sprays	Waterproofing and related aerosol sprays	236–240
Hydrocarbons	Aspiration of low-viscosity materials, “fire-eating”	19, 246, 248, 253, 255
Hydrogen sulfide	Sewers and manure pits; fossil fuel and geothermal production	306, 309–311
Mercury vapor	Gold extraction, heating cinnabar	174–181
Methyl bromide	Pesticide fumigant	304, 304
Methyl isocyanate	Pesticide manufacturing	312, 314
Methyl isothiocyanate	Breakdown product of metam sodium fumigant	315, 316
Mustard gas	Chemical warfare agent	59, 141–143
Nickel carbonyl	Nickel processing, metal reclamation	182–186
Nitrogen dioxide	Silage; combustion; explosives; welding; nitric acid mixes	9, 52, 104, 105, 108
Organic dusts/aerosols	Contaminated dust or bioaerosol generation	22, 217, 222, 223
Organophosphates	Pesticide application; chemical warfare	131, 132
Ozone	Bleaching; water treatment; plasma welding	10
Paraquat	Herbicide skin contamination or ingestion	20, 259
Phosgene	Chlorinated solvent breakdown by-product	11, 16
Phosphine	Fumigation with aluminum or zinc phosphide, microelectronics	330–332
Sulfur dioxide	Refrigeration; cement manufacture; mining; pulp paper mills	8, 118–120
Tributyltin (bis[tributyltin] oxide)	Paint additive for mold inhibition	196
Vanadium	Ore processing; fossil fuel by-product, catalyst use	192, 193
Zinc chloride	Smoke bombs (“white smoke”)	162, 166
Zinc oxide fume	Welding galvanized steel; brass casting	199, 200, 216

can be generated from liquid bleach containing hypochlorite or from dry powdered bleach containing chlorinated phosphate. In either liquid or powdered bleaches, the chlorine gas is liberated on contact with acids in common household products containing muriatic (i.e., hydrochloric), phosphoric, or hydrofluoric acid⁸⁵ or in industrial settings.⁴³ In contrast, mixing chlorine-containing products with ammonia leads to release of chloramines (monochloramine [NH₂Cl] and dichloramine [NHCl₂]) and related chemicals, especially nitrogen trichloride (NCl₃), chemicals whose irritant effects are attributed to in situ pulmonary reactions releasing chlorine, hypochlorous acid, and ammonia.^{85,90,91} In swimming pools, inadvertent mixing of the chlorinated water with nitrogen donors can also happen, with potential irritant effects attributed to nitrogen trichloride in particular.^{90,92} Chloramines evolved from chlorine and ammonia mixing should not be confused with Chloramine-T (sodium-N-chlorine-p-toluene sulfonamide), a disinfectant that can act as a chemical sensitizer leading to allergic asthma and other anamnestic responses.⁹³

Irritant effects after inhalation of *hypochlorite* aerosols in confined spaces without a history of combining products (not an uncommon scenario when cleaning bathrooms) can also be associated with irritant effects. Similarly, in certain industrial operations, hydrochloric (hydrogen chloride in water) or hypochlorous acid aerosols are also respiratory irritants. Chlorine exposure can also take place in specific industrial processes that use inorganic chlorine derivatives; worthy of particular mention are chlorine dioxide (used in pulp paper processing),⁹⁴ chlorinated silanes (gases used in microelectronics),⁹⁵ reactive metal halides (e.g., titanium or antimony chlorides),¹⁸ and thionyl chloride (which breaks down to yield hydrogen chloride and sulfur dioxide).^{54,96}

For chlorine and related chemicals, the acute respiratory response corresponds to the effective dose delivered to the lungs. For chlorine, as for irritant gases generally, the dose response has been presumed to be equivalent for any given cross-product of concentration and exposure time (Haber law), although experimental data indicate that this

relationship may be more variable.⁹⁷ All of these compounds appear to share a final common toxic pathway. As noted in the general discussion of acute toxicant inhalation, water solubility is an important determinant of the dose reaching the lower airways. For chlorine, chlorine dioxide, chloramines, and nitrogen trichloride, their lower solubility favors deeper penetration with a more effective delivered dose compared with an equivalent inhalation of agents with a higher solubility such as acid aerosols. However, exposure to any of these compounds is associated with some degree of immediate mucous membrane and upper airway irritation. In fact, the absence of acute irritant effects is not clinically consistent with chlorine gas or related exposures.

Chlorine inhalation may manifest any of the full spectrum of respiratory tract irritant effects, from minor mucosal responses to upper airway responses to diffuse alveolar damage.^{78-88,98} Persistent airway hyperresponsiveness after irritant exposure has been associated particularly with chlorine gas and chlorine-containing products, although this association may have more to do with the frequency of exposure to chlorine rather than to any particular effect of chlorine on the airways.^{14,43,48,49} Human experimental studies are inconsistent as to whether persons with underlying airway hyperreactivity may be more sensitive to chlorine.^{99,100}

Use of inhaled bronchodilators and inhaled steroids may be indicated for both acute and residual bronchospasm following chlorine inhalation, consistent with general principles of management addressed previously. Although several case reports and series have touted the potential benefits of nebulized sodium bicarbonate inhalation in the acute treatment of chlorine or chloramine inhalation, the efficacy of this intervention has never been assessed in a controlled trial.^{91,100,101} One small controlled trial administered inhaled bicarbonate 3 months or more after exposure in irritant-induced asthma and described some benefit.¹⁰²

OXIDES OF NITROGEN, OZONE, SULFUR DIOXIDE, AND ACID AEROSOLS

These inhalants are major air pollutants; the effects of low-level exposure are discussed in detail in Chapter 74. When they are inhaled in high concentrations, these irritants cause acute lung injury. Because of their lower solubility and thus their lower incidence of upper airway symptoms, ozone¹⁰ and, even more commonly, nitrogen dioxide, may be associated with a longer exposure with a greater predilection for lung injury.¹⁰³ Nonetheless, with sulfur dioxide and acid aerosols, despite their high solubility, a sufficient intensity of exposure can also lead to diffuse alveolar damage.

High-intensity exposure to *oxides of nitrogen* can take place through decomposition of organic matter and other sources. Examples of exposure scenarios include nitrogen dioxide-induced lung injury among farmers (also known as silo filler's disease),^{52,104,105} use of internal combustion engines in enclosed spaces (with large outbreaks associated with ice resurfacing equipment used in indoor skating rinks),^{9,106-108} thermal degradation of polymers (e.g., in structural fires),³⁴ toxic gas produced by the detonation of explosives,^{56,109} the release of gas through reactions of

nitric acid breakdown in air or in reaction with metals or organic materials,¹¹⁰⁻¹¹² welding by-products, particularly when "gas-shielded" techniques are employed (manual inert gas welding or tungsten inert welding),¹¹¹ and the release of compressed nitrogen dioxide gas.¹¹⁴ Historically, the detonation of explosives has been one of the most important sources of exposure to nitrogen oxides.¹⁰⁹ Nitric oxide, an inhalant used therapeutically, breaks down to nitrogen dioxide in the presence of oxygen and, thus, must be monitored with appropriate delivery devices to avoid exposure to the potentially toxic nitrogen dioxide.¹¹⁵

High-intensity occupational ozone exposure is unusual, but it can happen with welding conditions similar to those associated with oxides of nitrogen.¹¹³ More recently, ozone in water treatment and in pulp paper bleaching has also emerged as a health issue; in the latter industry, there is often concomitant exposure to chlorine dioxide.^{116,117}

Important sources of high-level sulfur dioxide exposure include mining and ore refining,⁸ Portland cement manufacturing,¹¹⁸ sulfur treatment of fruit,¹¹⁹ and industrial releases.¹²⁰ Historically, sulfur dioxide has been and continues to be important in sulfite process pulp paper processing, where acute gas releases are superimposed on chronic lower-level exposure.^{116,117,121} In the past, sulfur dioxide was also a common refrigerant.¹²²

In ambient air pollution, sulfuric acid is an acid aerosol of primary concern; in various occupations, sulfuric acid can also be encountered at high levels. Workers can be exposed to sulfuric acid through both direct use and the breakdown of a highly toxic industrial chemical, dimethyl sulfate.^{123,124} A number of other inorganic and organic acid vapors and aerosols are also important potential causes of acute lung injury, including chromic,¹²⁵ acetic,¹²⁶ formic,¹²⁷ and hydrofluoric acids.^{112,128,129} *Hydrofluoric acid* (hydrogen fluoride) inhalation, in addition to nonspecific irritant effects, can induce clinically significant hypocalcemia, which is thought to result from the formation of insoluble calcium fluoride.¹³⁰ People can be exposed to hydrofluoric acid in manufacturing of both microelectronics and phosphate fertilizers, in household use of hydrofluoric acid rust removal agents (the mixture of which with hypochlorite bleach can evolve both chlorine and hydrogen fluoride), and in the incomplete combustion (pyrolysis) of fluorinated polymers.¹³¹ Exposure to hydrogen fluoride is a chronic problem in the aluminum smelting industry.¹³² Hydrogen fluoride is also released as a breakdown product of sulfur hexafluoride, an electrical insulating liquid chemical used in equipment.¹³³

MILITARY AND CROWD CONTROL AGENTS

Overview

Unfortunately, chemical warfare agent exposures are not of mere historical interest.^{88,134,135} Not only can sporadic exposures result from contact with discarded ordinance,¹³⁶ but more importantly, exposure can be widespread through the use of chemical warfare agents in acts of terrorism or in conventional military conflicts. Such risks have raised the specter that the diagnosis and management of such toxicants will again become clinically relevant. There have been a number of reviews of the general aspects of this

question.¹³⁷⁻¹³⁹ The goal of this section is to address individual chemical agents, including other military and crowd control agents that are not warfare chemicals per se, focusing on their respiratory target organ toxicity. Biologic warfare agents of relevance to the respiratory tract are covered elsewhere (see Chapter 40).

Sulfur Mustard

Of the major World War I chemical weapons, only sulfur mustard (so called “mustard gas,” although not a true gas in physical state) has been used “militarily” since World War II. Classified as a vesicant because of blistering induced by skin contact, mustard gas inhalation causes severe respiratory injury. Largely on the basis of the Iranian experience of their Iraqi war veterans, sulfur mustard survivors can exhibit residual tracheobronchitis, asthma, bronchiectasis, bronchotracheomalacia, BO, and fibrosis.^{59,140-143} Nitrogen mustards were sulfur mustard derivatives originally developed for military purposes but later applied medically; nonetheless, occupationally related acute lung injury has been reported through industrial release.¹⁴⁴

Phosgene

Another World War I toxic gas, phosgene, is currently encountered as a chemical industry process chemical and as a thermal breakdown product or ultraviolet photoreactant of chlorinated solvents (e.g., methylene chloride).^{11,145} An occult cause of exposure can be inadvertent phosgene production from welding metals “degassed” with solvents.¹¹³ Phosgene is the prototypic deeply penetrating inhalant exhibiting a delayed onset of symptoms (12 to 24 hours after exposure).^{17,30,146,147,147a}

Chloropicrin

Chloropicrin, another World War I gas, is a low-threshold irritant currently encountered in chemical manufacturing and as a component of fumigants.¹⁴⁸⁻¹⁵⁰

Neurotoxicants

The modern chemical warfare armamentarium is dominated by systemic toxicants developed from organophosphate pesticides (which are discussed later in “Pharmacologic Syndromes”); the nerve agent “VX” is prototypical.^{151,152} These highly lethal neurotoxins have important respiratory effects, including manifestations of both muscarinic receptor stimulation (bronchorrhea and bronchospasm) and nicotinic receptor depolarization blockade (respiratory muscle paralysis); treatment is based on reversing enzyme inhibition and countering the effects of acetyl cholinesterase excess.¹⁵³

Chloroacetophenone (Mace), Other Tear Gas Agents, and Zinc Chloride

Crowd control agents (“tear gases”), as opposed to the war gases, are intended to incapacitate persons via immediate mucous membrane irritation.¹⁵⁴ The agents in greatest use worldwide are chloroacetophenone (“mace”) and ortho-chlorobenzamalonitrile.^{155,156} In addition to their mucous membrane effects, these agents have also been implicated in lower respiratory injury and even in persistent effects following high-intensity exposures (e.g., in enclosed buildings).¹⁵⁷⁻¹⁶⁰ Unlike tear gas, exposure to smoke bomb releases

(sometimes referred to as “white smoke”) can cause severe lower respiratory injury by exposure to the potent respiratory irritant, zinc chloride fume, created through a pyro-technic reaction between hexachloroethane and zinc oxide.^{161,162} Military, police, and others who are exposed, often during ill-conceived training exercises, are at risk.^{27,161-166}

TOXIC METALS

Overview

Inhalation of certain metal fumes or metal vapors can cause an acute pneumonitis.¹⁸ Dangerous exposures to toxic metal fumes arise, in part, because these agents are not immediately irritating, analogous to the delayed symptoms after phosgene or nitrogen oxide gas inhalation. Patients typically present in respiratory distress 12 to 48 hours after exposure. Indeed, the exposure history often remains occult unless aggressively pursued. Metal pneumonitis from these materials also can include fever as a clinical manifestation of this toxic syndrome. However, the term *metal fume fever* should not be used in this context.¹⁶⁷ The toxic mechanism generalizable in heavy metal pneumonitis is presumed to be inhibition of enzymatic and other critical cellular functions.

Cadmium, Mercury, and Nickel

The three metals most important clinically in lung injury are cadmium, mercury, and nickel (the latter in the form of nickel carbonyl). For cadmium, exposure typically takes place through welding, brazing (high-temperature soldering) or flame-cutting metal, or working with molten metal under conditions of inadequate ventilation.¹⁶⁸⁻¹⁷¹ In welding, brazing, and flame-cutting, the usual source of cadmium is the welding rod, brazing solder, or a metal coating, rather than the base metal itself.¹¹³ In areas of the world where jewelry is made at a cottage industry level, cadmium use in silver-working can present a particular exposure risk.^{172,173}

High levels of the relatively volatile metal mercury can be generated effectively from many nonenclosed operations, most notably through heated metal reclamation processes (e.g., home refining of mercury-gold amalgams or even reclaiming of mercury from electronic equipment).¹⁷⁴⁻¹⁸¹ Exposure has also been reported after burning mercury sulfide (Chinese red cinnabar) and mercuric oxide for medicinal purposes.¹⁷⁹ Chelation treatment has not been shown to be effective in heavy metal pneumonitis due to mercury.

Nickel carbonyl is an organic metal derivative and potent pulmonary toxicant, with exposure during nickel refining, during manufacturing processes in which it is used as a catalyst or intermediate, or during metal recycling or reclaiming operations.¹⁸²⁻¹⁸⁶ A case report of fatal nickel fume inhalation from a metal spraying operation that was nickel carbonyl free suggests that under certain conditions inorganic nickel can also cause acute lung injury.¹⁸⁷ Although specific metal chelators have been advocated in nickel-related lung injury, the evidence in support of this in clinical practice (i.e., after illness is manifest) is equivocal. The agent dithiocarb (diethyldithiocarbamate) has been

used as a chelating antidote for nickel carbonyl pneumonitis, on the basis of supportive animal data, although its benefits are most clear-cut when administered soon after exposure (e.g., before the time clinical illness would be manifested); disulfiram has been suggested as a potential alternative treatment, although experimental data to support this practice are weak as well.¹⁸⁸

Other Metals

Other metals, including antimony, manganese, and beryllium, are sometimes cited as causes of acute lung injury consistent with metal pneumonitis, but there are few reports in the past 50 years providing documentation of such disorders.⁷ A recent case report implicated copper dust inhalation with acute lung injury.¹⁸⁹ Osmium tetroxide is a potent respiratory irritant with terrorist weapon potential; fortunately, to date experience with human inhalation exposure has been limited.¹⁹⁰ Cerium oxide is another metallic exposure of theoretical concern because of its potential use as a fuel additive and its capacity to cause acute inhalation injury experimentally.¹⁹¹

Two other metal compounds are well-documented bronchial irritants in humans. Vanadium (typically as a metal oxide), which is encountered in metal processing and, in lower concentrations, as a fossil fuel by-product, causes acute bronchitis.¹⁹² Among boilermakers, vanadium-rich fuel oil ash is suspected to be a key exposure related to acute respiratory symptoms.¹⁹³ In a single case report, high-intensity exposure to ash from an oil-burning furnace was associated with diffuse alveolar damage; although vanadium was detectable in the residue, the toxic mechanism in this case was unclear.¹⁹⁴ In another case report, vanadium (as vanadyl pyrophosphate) was linked to pneumonitis.¹⁹⁵ Tributyltin (bis[tributyltin] oxide) is an organotin compound, which is an organic compound with one or more molecules of tin. Tributyltin, which is employed as a mildew and mold retardant, is also an acute airway irritant.¹⁹⁶

METAL FUME FEVER, POLYMER FUME FEVER, ORGANIC DUST TOXIC SYNDROME, AND OTHER INHALATION FEVERS

There are a number of febrile flulike pulmonary syndromes reflecting similar clinical responses to a diverse group of acute inhalational exposures.^{22,197} Their hallmark is chills, fever, malaise, and myalgia with onset 4 to 8 hours after intense inhalation of fumes or organic dusts.^{22,167,198} Common respiratory complaints include cough or mild dyspnea, but findings of chest radiographic opacities or hypoxemia are inconsistent with this disorder. Peripheral leukocytosis usually accompanies the syndrome; bronchoalveolar lavage shows a marked influx of neutrophils.¹⁹⁹⁻²⁰¹ These syndromes all are self-limited, resolving clinically within 12 to 48 hours. Inhalation fevers share a common feature of tachyphylaxis, with a blunted response to daily repeated inhalation (and hence the name “Monday morning fever” among both brass founders and cotton mill workers).^{22,202,203}

Signs or symptoms of pneumonitis should suggest alternative, more serious diagnoses, such as cadmium pneumonitis,^{169,170} hypersensitivity pneumonitis (see Chapter 64), active infection (in the case of water-source aerosols), or

inhalation of more toxic temperature-dependent fluoropolymer combustion by-products (which include hydrogen fluoride and perfluorobutylene [PFIB], which is more toxic than phosgene).^{204,205,205a} Toxic pneumonitis due to fluorocarbon-containing aerosol sprays is an exposure scenario distinct from polymer fume fever from exposure to fluoropolymer combustion by-products or from acute lung injury and are dealt with separately (see later).

Metal fume fever is associated with zinc oxide inhalation from welding galvanized metal or brass working.²⁰⁶ There is only limited clinical evidence that other metals (magnesium and copper) are capable of causing a similar response,^{167,207} and experimental data further discount magnesium as a potential cause of fume fever.²⁰⁸ Zinc oxide fume rarely has also been purported to cause an acute lung pattern in case reports of welding-related illness, but the likelihood of cadmium or nitrogen dioxide co-exposures make this uncommon association questionable.²⁰⁹ Further, controlled experimental human exposure data do not support this as a zinc oxide inhalation effect.²⁰⁰

Polymer fume fever is associated with thermal breakdown products of fluoropolymers (e.g., Teflon and related materials).^{198,210-212} The pathophysiologic mechanisms underlying the metal and polymer fume fever syndromes have not been established, but research suggests that pulmonary cytokines may play a key role.²¹³⁻²¹⁶

Organic dust toxic syndrome (ODTS) is associated with inhalation of materials contaminated with thermophilic bacteria and fungal spores, including wood chips,²¹⁷ straw,²¹⁸ silage,²¹⁹ seeds,²²⁰ grains and flour,²²¹ and textile raw materials.²⁰³ The increasing industrialization of agricultural processes, especially the use of animal confinement techniques or so-called *concentrated animal feeding operations* (CAFOs), is an additional source of exposure leading to ODTS, although these same settings also can produce irritant gases such as hydrogen sulfide and ammonia.^{222,223} ODTS has gone by various names, including pulmonary mycotoxicosis,²²⁴ silo unloader's syndrome,²¹⁹ and mill fever.²²⁵ One of the best documented historical outbreaks of ODTS was among individuals who worked with contaminated cotton mattresses.²⁰³ Inhalation of aerosols from contaminated water sources produces a self-limited febrile syndrome similar to ODTS. Some of these outbreaks are attributable to inhalation of *Legionella* species without actual infection (i.e., without clinical evidence of pneumonia) and are referred to as “Pontiac fever.”²²⁶⁻²²⁸ Contaminated aerosols causing inhalation fever syndromes can originate from saunas or hot tubs,^{229,230} commercial (industrial) humidifying systems,^{231,232} and metal machining cooling fluids.²³³ Along with these heterogeneous exposure scenarios, a variety of different names have been used for these syndromes, including humidifier fever,²³² sump bay fever,²³⁴ and bath water fever.²²⁹ As with ODTS, many of the same occupational and environmental conditions can lead to or be concomitant with cases of hypersensitivity pneumonitis and, more specific to waterborne aerosols, active respiratory infection. In addition to its self-limited nature, a key characteristic differentiating an outbreak of inhalation fever from other syndromes is its relatively high attack rate over a fairly short time period. As with metal fume fever and polymer fume fever, cytokines are presumed to be key mediators of the ODTS and water-borne aerosol-related

inhalation fevers, with endotoxin and related factors being key exposure variables.^{22,235}

FLUOROCARBON AEROSOL SPRAY PNEUMONITIS

Acute lung injury following inhalation exposure to commercial fluorocarbon-containing aerosol products is an important emerging syndrome first reported in the early 1990s.²³⁶ This syndrome is distinct both from fluoropolymer fume fever as previously discussed and from exposure to irritant by-products from higher-temperature thermal breakdown of such polymers. A key feature of fluorocarbon aerosol pneumonitis is the onset of symptoms within several hours after using a spray product containing fluorocarbon polymers. Exposure can take place in an occupational setting (e.g., construction) or, commonly, from use of over-the-counter products. These exposures can be relatively brief, with varying degrees of ventilation; importantly, exposure need not be in an enclosed space. Victims usually do not recall previous exposure; there is nothing in the condition to suggest a hypersensitivity mechanism. Application of multiple types of fluorocarbon-containing products have been linked to outbreaks; although waterproofing leather and fabric sprays have dominated the reports, other products include floor stain protector, rust-proofing spray, grout sealer, and ski wax.²³⁶⁻²⁴³ The clinical presentations manifest a range of severity consistent with varying degrees of non-specific acute lung injury; management is based on standard support care. The various descriptive labels for this condition, such as “horse rug lung” and “hill walkers’ lung,” can obscure the consistent pattern of the syndrome.^{239,244}

HYDROCARBON PNEUMONITIS AND “FIRE-EATER’S” LUNG

Hydrocarbon pneumonitis can follow oral ingestion of hydrocarbons and associated hydrocarbon aspiration. In the pediatric high-risk age group, aspiration can take place during ingestion from non-tamper-proof containers typically involving mineral spirits, mineral seal oil (common in furniture polish), lamp oil, kerosene (paraffin), turpentine (pine oil), gasoline, and lighter fluid.^{19,245-247} In adults, hydrocarbon aspiration associated with fuel syphoning represents an occupational hazard among diesel-powered heavy equipment and tractor operators.^{248,249} Even though these substances have systemic toxic effects such as central nervous system depression, life-threatening complications of ingestion are predominantly the result of concomitant hydrocarbon aspiration and subsequent pulmonary compromise, making the lung the target organ of concern in hydrocarbon ingestion. Pneumatocele is a recognized complication of hydrocarbon pneumonitis.²⁵⁰ In contradistinction to aspiration hydrocarbon pneumonitis, the toxicity of hydrocarbon (solvent) vapor inhalation manifests primarily in either central nervous system or cardiac effects. Major pulmonary target organ damage associated with acute hydrocarbon exposure by inhalation is unusual but has been reported.²⁵¹ Importantly, the lung also appears to be the target organ for the toxicity of intravenously administered hydrocarbons, an unusual but well-documented suicidal scenario.²⁵²

“Fire-eater’s lung” is an important variant of hydrocarbon pneumonitis.^{253,254} This syndrome typically involves adolescents or young adults becoming exposed through mishap during flame-blowing performances using a variety of different flammable materials. In addition to kerosene and gasoline, the toxicants include jet fuel and, in France, an aromatic hydrocarbon-enriched petroleum-distillate called “kerdan.”^{255,256} There has also been a case of citronella oil aspiration in a fire-eater.²⁵³ As with hydrocarbon pneumonitis in children, fire-eater’s lung can also be complicated by pneumatocele.²⁵⁷ Although the term *acute lipoid pneumonia* has been used to refer to the fire-eater’s lung syndrome, as well as in other acute aspirations, this is a misnomer.²⁵⁸

In both childhood and adult pneumonitis, hydrocarbons are aspirated at the time of the initial ingestion or subsequently with vomiting. The low viscosity of an ingested hydrocarbon is considered a major factor promoting aspiration, presumably for mechanical reasons.^{19,246} Although it has been theorized that hydrocarbon toxicity may involve disruption of surfactant, the chemical pneumonitis of the syndrome appears to be nonspecific.

PARAQUAT

Paraquat is a widely used herbicide and a potent toxin. Ingestion, rather than inhalation, is the typical route of exposure associated with human toxicity. There have been systemic reactions following skin exposure after direct exposure to the skin (e.g., soaking of the skin with paraquat) or when the skin integrity has been breached (e.g., preexisting skin lesions or burn). The theoretical risk of smoking contaminated materials has never been established.

Most paraquat deaths result from suicidal intent.^{20,259,260} Paraquat ingestion is a relatively uncommon method of suicide in the United States, but its incidence is greater in a number of other countries, perhaps related to patterns of crop utilization and ease of access.^{259,261} Although paraquat ingestion leads to acute gastrointestinal tract necrosis and multiorgan failure, the lung is the target organ for toxicity among those surviving the immediate postingestion period. Diquat, a related dipyridyl herbicide, does not cause the lung injury associated with paraquat, although poisoning can lead to renal failure and cerebral hemorrhage.²⁶²

The pulmonary toxicity of paraquat, in contrast to its gastrointestinal effects, does not reflect caustic irritant injury. The major lung effect of paraquat toxicity is the development of pulmonary edema, usually observed 24 to 48 hours after ingestion. The pulmonary edema may evolve to a condition resembling acute respiratory distress syndrome, associated with histopathologic findings similar to those of diffuse alveolar damage, which may progress to an accelerated, chemically induced pulmonary fibrosis. After stabilization following acute multiorgan toxic effects, disease progression is marked by rapidly worsening respiratory distress, hypoxemia, and a restrictive ventilatory defect, with decreased lung compliance and diffusing capacity, ending in death from ventilatory failure within days to weeks.^{20,259} Survivors may demonstrate modest and slow improvement in lung function.²⁶³

The mechanism of paraquat toxicity is attributed to the generation of superoxide radicals that may be partly iron dependent. Consistent with an oxidant mechanism, supplemental oxygen and radiation therapy may worsen the outcome; there are no known antidotes for paraquat poisoning, and enhanced elimination as by hemoperfusion has not demonstrated a clear benefit.^{20,259} Plasma paraquat levels can be determined and may have a use in predicting outcome.²⁶⁴ Data suggest a possible therapeutic benefit from immunosuppression, but this awaits confirmation through controlled clinical trials.^{21,259} Death results from multiorgan failure, which usually happens within 1 to 2 weeks but may be observed up to 6 weeks after ingestion.

SMOKE INHALATION

The generic term *smoke inhalation* includes potential exposure to a wide array of substances because of the complex chemistry of heat decomposition and pyrolysis.^{34,265} *Pyrolysis* refers to the thermal decomposition of organic material without the involvement of oxygen and is a common component of burning buildings where oxygen is limited. Pyrolysis produces a variety of gases and a physical product such as charcoal. Although anoxia from carbon monoxide, cyanide, and oxidants represents a major manifestation of toxic insult from acute smoke inhalation, this nonpulmonary target organ effect is not covered here. However, a number of chemical irritants produced as pyrolysis by-products do have significant potential pulmonary toxicity. In contrast to thermal injury to the respiratory tract, which is typically limited to upper airways, with laryngeal edema the major potential medical management problem,^{266,267} inhalation of the smoke from fires can affect the entire respiratory tract through irritant injury.

In certain cases, irritant chemicals from fires are released as preformed substances but, most commonly, the toxins are formed *de novo*. These irritants are produced by the thermal degradation of both natural and synthetic polymers. The predominant by-products of heat breakdown are determined by the nature of the polymers consumed, temperature of the fire, and availability of oxygen.²⁶⁸

Generally, polymers do not break down to their monomer precursors, although residual monomers can be evolved under certain circumstances. For example, when polyvinyl chloride is burned, hydrogen chloride is released rather than the monomer, vinyl chloride. Many of the specific chemical irritants that can be released as common thermal breakdown by-products are addressed elsewhere in this chapter. These include the following: hydrochloric acid (hydrogen chloride), hydrofluoric acid (hydrogen fluoride), and other acids; ammonia; phosgene; and oxides of nitrogen. The zinc chloride “smoke” of smoke bombs (in contrast to the heterogeneous character of “natural smoke”) is also discussed separately.

Aldehydes merit specific attention. They are a common cause of high-intensity irritant lung injury from the smoke from fires. These chemicals include formaldehyde, acetaldehyde, and acrolein. The most severe irritant, *acrolein* ($\text{CH}_2 = \text{CHCHO}$), is least familiar to most health care providers. Acrolein, a highly reactive chemical and key toxicant in smoke inhalation injury, is formed as an important pyrolysis product of both synthetic (e.g., acrylic) and natural poly-

mers.^{269,270} In addition to *de novo* formation as a combustion by-product, acrolein is also intentionally manufactured and used as a pesticide; its use as an aquatic herbicide to facilitate water flow in irrigation canals can lead to human inhalation exposure with irritant effects.²⁷¹

The general considerations concerning irritant exposure discussed previously, including air concentration and water solubility, come into play in smoke inhalation. These factors are further complicated by the potential interactive effects of multiple simultaneous exposures, as well as the modifying impact of physical cofactors such as airborne respirable particulates (e.g., soot) that may serve as adsorbent carriers facilitating deep lung penetration. In practice, detailed exposure data delineating the irritant contents of a specific smoke exposure are rarely available. Information that may help to elucidate exposure conditions include identity of the products involved (e.g., specific synthetic polymers, if known), history of inhalation within an enclosed or confined space, evidence of thermal injury, and carboxyhemoglobin and methemoglobin levels as markers of inhalation severity based on other concomitant exposures (carbon monoxide and oxidants).

Firefighters (both urban and wildland) and nonoccupationally exposed victims of irritant smoke inhalation have proved to be important groups in which to study acute inhalational syndromes. Large-scale conflagrations (e.g., urban “wildland” fires^{271a,271b}) can expose substantial numbers of people to irritant combustion by-products, as can smoke drift from intentional burning of agricultural residue. Studies of such populations after smoke inhalation have demonstrated acute and persistent airflow obstruction and increased nonspecific airway hyperresponsiveness.²⁷²⁻²⁸⁰ Bronchiectasis and BO have both been associated with combustion by-product exposure.^{55,57} The acute respiratory effects and potential sequelae of exposure to the plume generated by the destruction of the World Trade Center may relate to other factors such as alkaline (high-pH) dust from concrete, gypsum, and glass fibers, rather than to standard smoke particulate.²⁸¹

PHARMACOLOGIC SYNDROMES

Certain natural and synthetic chemical exposures affect the lung by specific mechanisms consistent with known pharmacologic actions. These chemicals are site-specific for key cellular functions leading to adverse respiratory effects. As noted previously, the most potent chemical warfare agents act through acetyl cholinesterase inhibition, with profound impacts on respiratory function.^{151,152} Similar, albeit less potent, agents have widespread use as agricultural chemicals. Both organophosphate and carbamate pesticides lead to respiratory compromise as a principal toxic effect. For example, in one case series, a considerable number of poisonings from these pesticides led to respiratory failure, accompanied by a high case-fatality rate; in contrast, all the patients without concomitant respiratory failure survived.²⁸²

Inhaled capsaicin, of interest as a research tool to study substance P-mediated effects, is associated with cough in occupational settings (e.g., in chili pepper processing).²⁸³ When used as a “personal defense spray,” respiratory irritation has been reported, although ocular problems are more

common.^{284,284a} Brevetoxin is a toxin produced by dinoflagellates associated with “red tides.” Environmental inhalation exposure from airborne aerosols of red tide due to wind and surf action causes cough, sneeze, and wheeze.²⁸⁵⁻²⁸⁷ For lifeguards, brevetoxin health effects represent a source of occupational respiratory morbidity, including work loss.²⁸⁸ The toxin appears to act by stimulating sodium channels in the lung. Respiratory irritation may also be a manifestation of *Pfiesteria* dinoflagellate toxin inhalation (although potential neurotoxicologic effects have been of more concern).^{289,290}

OTHER INHALANT EXPOSURES

Ammonia

Anhydrous ammonia is a gas at room temperature and ambient pressure, although ammonia is more commonly encountered in aqueous form, as in cleaning solutions. Potential sources of ammonia gas exposure include incidents in the chemical industry and in hazardous transportation, commercial refrigeration systems, and farming (e.g., fertilizer).^{7,291-295} Anhydrous ammonia has also been released from illicit methamphetamine laboratory operations, although such exposures are often in the context of conflagrations with concomitant thermal burns and other coexposures.^{296,297} Ammonia has prominent irritant warning properties (such as burning eyes). It is linked with lung injury chiefly in settings of overwhelming exposure or where immediate escape has not been possible. Both asthma and bronchiectasis have been documented after ammonia exposure.^{7,294} Acute ammonia exposure has also been reported to have residual upper airway effects, including decreased olfactory acuity.³⁷ Death may result from laryngeal edema and airway obstruction, acute pulmonary edema, or complications of the pneumonic process (e.g., bacterial superinfection). A case of lung transplantation within a year after ammonia inhalation has been reported.²⁹⁸

Bromine and Methyl Bromide

Bromine is an irritant halogen. It is usually handled as a liquid rather than as a gas, but it vaporizes readily. Sources of bromine exposure other than environmental releases include chemical synthesis and water purification.^{58,299-302} Bromine is a more potent irritant than chlorine and approximately 100 times more irritating than ammonia.³⁰³ *Methyl bromide* is a major industrial fumigant with far-greater potential for public exposure. Methyl bromide is also a potent respiratory irritant, but the central nervous system may represent the more important target organ in typical exposures.^{304,305}

Hydrogen Sulfide

Hydrogen sulfide is a common by-product of petroleum extraction and refining, as well as a potential hazard from the breakdown of organic materials (hence, its common name, “sewer gas”); overexposure can result from work in confined spaces, submersion in manure pits,³⁰⁶ or proximity to geothermal and volcanic sources.³⁰⁷ Hydrogen sulfide is a respiratory irritant, but it is an even more potent cytotoxic asphyxiant, impairing cytochrome oxidase and cellular respiration. Therefore, in cases of severe hydrogen sulfide exposure, rapid cardiovascular collapse and death often

overshadow any pulmonary organ effects, although an acute lung injury pattern can be present in those surviving long enough to receive intensive supportive care; irritant symptoms as a predominant feature may be of greater relevance in lower-intensity exposures.^{306,308-311}

Methyl Isocyanate and Methyl Isothiocyanate

Methyl isocyanate (MIC) use is restricted to a narrow industrial application in the synthesis of pesticides. The mass fatalities at Bhopal, India, make MIC an important toxin for historical reasons. The toxicity of MIC was the result of its severe irritant properties leading to pulmonary edema.³¹²⁻³¹⁴ No cyanide-mediated mechanism was involved. Methyl isothiocyanate, a breakdown product of the soil fumigant metam sodium, is an irritant chemically related to MIC that was also involved in a mass exposure episode, although less severe than the MIC release at Bhopal, and has also been associated with respiratory symptoms following agricultural application.^{315,316} The isocyanates associated with urethane, such as *toluene diisocyanate* (TDI), *diphenylmethane diisocyanate* (MDI), and *hexamethylene diisocyanate* (HDI), are pulmonary irritants but are primarily of concern because of their induced sensitization (see Chapter 72).

MISCELLANEOUS EXPOSURES

A number of other occupational and environmental agents result in acute pulmonary syndromes. Examples of such exposures include diethylaminoethanol and cyclohexylamine (both anticorrosive boiler additives)^{317,318}; amitrole and glyphosphate (both common herbicides)^{319,320}; sodium azide (used in a variety of chemical applications but important as a potential inhalant through automobile airbag deployment)³²¹; diazomethane, which is explosive but also highly toxic to the lung with a delayed onset similar to that of nitrogen dioxide^{322,323}; diborane (an irritant gas used in manufacturing microelectronic equipment)^{324,325}; barium (inhalation can cause bronchospasm and respiratory muscle weakness in addition to life-threatening hypokalemia)³²⁶; and hydrogen selenide (an irritant gas used in several industrial processes, as well as being a potential metal processing by-product).^{327,328} A recent outbreak of severe lung injury in Korea was linked to the room humidifier water being treated with two biocides: *polyhexamethyleneguanidine* (PHMG) and oligo(2-(2-ethoxy)ethoxy-ethyl) guanidinium chloride.^{329,329a}

Phosphine is an important agricultural fumigant with pulmonary and systemic toxicity that is generated on site as a gas given off by moisture coming in contact with solid form aluminum or zinc phosphide (e.g., in grain storage facilities or railway grain transport cars, where bystanders can be exposed).^{330,331} Ingestion of the parent material by animals can also lead to exposure among treating veterinary personnel.³³² Phosphine also has industrial applications, particularly in the production of microelectronics. Acetic anhydride (used in making epoxy and other resins) has also been associated with acute lung injury following acute inhalation.³³³ A distinctly different pattern of injury is associated with a related epoxy chemical, trimellitic anhydride, which causes severe pulmonary hemorrhage after subacute exposure.¹³ Carbon dioxide, although a bulk asphyxiant and not a respiratory irritant, causes shortness

of breath and induces tachypnea; people can be exposed through natural geologic sources and dry ice sublimation in an enclosed space.³³⁴⁻³³⁶ Baby (talcum) powder inhalation can cause a pediatric acute pneumonitis within hours of heavy exposure; infant inhalation of nontalcum powders has also led to pneumonitis.³³⁷⁻³³⁹ Paraphenylenediamine is a dye used to color hair and can also be admixed with henna as a temporary tattooing agent; its ingestion as an agent of self-harm is common in Asia and Africa. In addition to rhabdomyolysis and renal damage, this chemical has a particular propensity to cause angioedema leading to airway obstruction.²³

Naturally occurring sources of exposure can also be associated with acute and subacute lung responses, although these syndromes are poorly characterized. Epidemiologically, *Stachybotrys chartarum* (atra) mold growth in water-damaged residential structures was initially linked to a cluster of cases of pulmonary hemorrhage in infants, although the association was later retracted in a follow-up review by the U.S. Centers for Disease Control and Prevention.^{340,341} Other case reports have occasionally linked other molds or mold by-products with lung injury (as opposed to self-limited ODTs, discussed previously).³⁴²

Lycoperdonosis is a potentially severe, acute pulmonary syndrome following intentional inhalation (sometimes as a natural medicinal treatment) of puffball mushroom (*Lycoperdon*) spores; in addition to human illness, fatal inhalation in pet dogs is a well-characterized veterinary syndrome.³⁴³⁻³⁴⁵ The pathophysiology of the syndrome is not understood, but its high attack rate with heavy exposure suggests a toxic rather than an allergic or infective mechanism.

Key Points

- Short-term inhalation exposures to toxic substances have important effects on the lung as the target organ for damage.
- Acute lung toxicity results from a variety of exposures but, nonetheless, is manifest by a narrow repertoire of injury.
- Although modified by the solubility and other physical properties of the toxic agent, injury largely depends on the intensity and duration of exposure.
- Extensive injury can lead to acute pulmonary edema and diffuse alveolar damage.
- Specific exposures of importance include chlorine, oxides of nitrogen, sulfur dioxide, acid aerosols, toxic metal fumes, and pyrolysis by-products.
- Aside from acute irritant or toxic lung insult leading to airway injury and diffuse alveolar damage, other patterns of acute responses include the inhalation fevers (which are self-limited and appear to be cytokine-mediated) and certain target-specific effects, such as those elicited by cholinesterase inhibition.
- Exposure by *ingestion* of some substances (e.g., hydrocarbons and paraquat) can cause important acute pulmonary target organ toxicity.

THORACIC TRAUMA**INTRODUCTION**

Among trauma victims, thoracic trauma is the second most common cause of death in the field and the third most common cause of death in patients who make it to the hospital. In civilian trauma, the most common mechanism is blunt trauma and the most frequently encountered injuries (i.e., hemothorax and pneumothorax) are seen in 20% of patients.¹ The majority require only tube thoracostomy for definitive treatment; however, up to 15% of these patients will require operative intervention,¹ whether immediate (resuscitative), urgent, or delayed. Overall mortality in patients with thoracic trauma is about 10%, with a low Glasgow Coma Scale score exerting the strongest influence on mortality.¹ Additional predictors of poor outcomes include increasing age, mechanism of blunt injury, increasing number of ribs fractured, and concomitant long bone extremity fractures.¹

INDICATIONS FOR RESUSCITATIVE THORACOTOMY

Patients who arrive without signs of life may benefit from *emergency department thoracotomy* (EDT) or “resuscitative” thoracotomy depending on the amount of time elapsed since the loss of vital signs (<15 minutes for penetrating trauma; <10 minutes for blunt trauma).^{2,3} The goal of this procedure is to restore spontaneous circulation by rapid repair of intrathoracic injuries or release of pericardial tamponade, and occlusion of the descending thoracic aorta to divert perfusion to the brain and heart. Internal cardiac massage with injection of intracardiac medications may also be indicated. In cases of bronchovenous air embolism, clamping of the pulmonary hilum prevents further propagation. Because resuscitative thoracotomy should always proceed to the operating room for definitive repair, it should not be attempted without a surgeon immediately available. Rhee and colleagues reported that the overall survival rate after EDT is 7.4%, with a survival rate of 15% among all patients with penetrating injuries and 35% among patients with penetrating cardiac injuries.⁴ On the contrary, survival rates are very low (2%) after blunt traumatic arrest.⁴

It is important to perform an initial cardiac ultrasound, because EDT can be considered futile if asystole is the presenting rhythm and pericardial tamponade is absent.³ In patients with appropriate indications, aggressive efforts are justified, because functional long-term outcomes in survivors are excellent. More than half of survivors are discharged home from the hospital, and more than 75% have normal cognition, are ambulatory, and have no evidence of posttraumatic stress disorder.⁵ However, inappropriate EDT results in no survival benefit, wasted use of resources, and exposure of health care workers to needle-stick and bone fragment injuries.⁶

INDICATIONS FOR URGENT THORACOTOMY

Commonly accepted indications for urgent thoracotomy include any of the following: initial chest drain output of 1500 mL; greater than 1500 mL output in the first 24 hours after injury; more than 200 mL bloody output per hour for 3 consecutive hours; massive air leak (present during all phases of respiration, associated with inability to reexpand the lung or affecting ventilation secondary to loss of tidal volume); or hypotension.⁷ Rarely, a patient has sudden cardiovascular collapse or new neurologic symptoms, typically after the patient is placed on positive pressure ventilation, that are consistent with air embolism and require urgent thoracotomy.

INDICATIONS FOR DELAYED THORACOTOMY

Delayed thoracotomy is performed several days after injury in stable patients, usually for retained hemothorax, trapped lung, persistent air leak, or rib fixation (discussed later).

THORACIC CAGE INJURIES**Rib Fractures**

Rib fractures are seen in 10% of hospitalized trauma patients.^{8,9} The morbidity of rib fracture pain is underappreciated; one third of patients require hospitalization for pain control, and pneumonia develops in another third of these patients.¹⁰ The true incidence of rib fractures is likely higher, in that, a supine chest radiograph is, at best, about

From Pressley CM, Fry WR, Philp AS, Berry SD, Smith RS. Predicting outcome of patients with chest wall injury. *Am J Surg* 204:910-914, 2012.

50% sensitive for detecting rib fractures. Chest *computed tomography* (CT) (eFig. 76-1) is much more sensitive and can also evaluate for other occult injuries.⁸ In general, ribs tend to fracture at their weakest structural point (the posterior angle) or directly at the point of impact.¹¹ They are rarely the sole injury, and 50% of patients with rib fractures have other significant injuries.¹⁰ In a patient with lower rib injury (9th through 12th), abdominal solid organ injury (spleen or liver) should be ruled out.

Pressley and colleagues developed a simple scoring system based on initial clinical findings (age, number of fractured ribs, severity of *pulmonary contusion* [PC], unilateral vs. bilateral rib fractures), to predict the likelihood of requiring mechanical intubation or *intensive care unit* (ICU) admission¹² (Table 76-1). The authors found that a patient with a score of 7 or 8 had a high probability of death, need for ICU admission, and a need for mechanical ventilation. Similarly, a score of greater than 5 predicted the need for a longer hospital stay and prolonged mechanical ventilation. Other studies found that an increasing number of rib fractures correlates to increasing *ICU length of stay* (LOS), hospital LOS, and mortality.^{13,14}

Treatment for the vast majority of patients with rib fractures is supportive care, consisting of aggressive pain control and pulmonary rehabilitation. Deep breathing facilitates clearance of secretions to reduce the incidence of pneumonia. Analgesic options include oral analgesics (including opioids), intermittent intravenous analgesics, patient-controlled analgesia, *thoracic epidural analgesia* (TEA), intrapleural blocks, intercostal blocks, and thoracic paravertebral blocks.¹⁵ Non-opioid analgesic options include acetaminophen, nonsteroidal anti-inflammatory drugs (including ketorolac), anticonvulsants such as gabapentin, and topical lidocaine patches.¹⁶ Numerous small, single-center trials have reported that pain control with TEA, compared with intravenous opioids, results in superior outcomes as measured by less pain, improved pulmonary function, fewer ventilator days, fewer infections, fewer pulmonary complications, shorter ICU LOS, and shorter hospital LOS.¹⁷⁻²⁴ Furthermore, TEA may also attenuate the postinjury inflammatory response.^{22,25} At present, TEA is the preferred analgesic modality for pain secondary to blunt

Figure 76-1 Relationship between the number of rib fractures and mortality. In a retrospective study of patients admitted to trauma centers, mortality increased with increasing number of rib fractures, an easily quantifiable measure of trauma severity. At each number of rib fractures, mortality for those older than 65 years was greater than that for those younger than 65. (From Stawicki SPG, Michael D, Hoey, Brian A, et al: Rib fractures in the elderly: a marker of injury severity. *J Am Geriatr Soc* 52:805-808, 2004.)

thoracic injury.²⁶ However, TEA is underused, with studies reporting less than 30% TEA use in eligible patients.²⁷ Epidural analgesia is not without risk, though, and side effects include hypotension, epidural hematoma, urinary retention, and epidural abscess.

Interestingly, a recent pooled meta-analysis did not find any benefit of TEA for duration of mechanical ventilation, ICU LOS, hospital LOS, or mortality.²⁸ For epidural analgesia to be of benefit, appropriate patient selection is paramount. Although absolute number of fractured ribs is predictive of the need for TEA, it is important to examine the patient carefully to determine whether pain is severe enough to cause respiratory embarrassment. In fact, one review reported that epidural analgesia was associated with *increased* complications and prolonged LOS in older patients.²⁹

Another underused analgesic option is the *thoracic paravertebral block* (TPVB) or paravertebral catheterization, which is easy to learn, has a greater than 90% success rate, and has a low incidence of side effects.^{30,31} When successful, TPVB has been shown to improve pain scores and pulmonary function tests.³² TPVB provides unilateral pain relief and thus is usually used only for patients with unilateral rib fractures; however, it is also useful when there are contraindications to TEA, such as coagulopathy, spinal fractures, or altered mental status.

In addition to pain control, a formalized multidisciplinary pathway that includes aggressive respiratory therapy and nutritional support has been shown to decrease ventilator days, LOS, infectious morbidity, and mortality among patients older than age 45 years with more than four fractured ribs.³³

Older patients with rib fractures are at especially high risk for complications: 15% require intubation, and pneumonia develops in up to 31%³⁴⁻³⁶ (Fig. 76-1). In patients older than age 45 years, morbidity sharply increases when more than four ribs are fractured.³⁷ Bulger and coworkers reported that patients older than 65 years with fractured ribs have double the morbidity and mortality rates compared with

younger patients with similar injuries.²⁷ Bedside vital capacity measurement can predict hospital LOS and identify those patients requiring discharge to an extended care facility.³⁸

Nonunion results in a small percentage of rib fractures and can manifest as chronic pain and discomfort.¹⁰ Typically, follow-up demonstrates that a significant proportion of patients have chronic persistent pain and impairment of both work and personal life.³⁹ In one study, patients with rib fractures had more disabilities at 30 days after injury than did patients with chronic medical illness. These patients with rib injuries missed an average of 70 days of work.⁴⁰ Two months after injury, more than 75% of patients with rib fractures reported some form of disability.⁴¹ Interestingly, the single most important predictive factor for long-term disability after rib injury was the initial intensity of pain. The total number of rib fractures and injury on both sides was not predictive.⁴¹

Flail Chest. A flail chest, also known as “stoved-in” or “crushed” chest, is the most severe form of blunt thoracic injury (see Chapter 98). The mortality associated with flail chest is up to 40%.⁴² Radiographically, it is defined as three or more consecutive ribs fractured in at least two locations. Clinically, a flail chest manifests as paradoxical incursion (rather than excursion) of the “floating segment” of chest wall during inspiration (Videos 76-1 and 76-2). Due to the significant energy transfer required to produce this injury, flail chest is almost universally accompanied by PC.

The management of flail chest has evolved over the past half century. Previously, it was believed that the paradoxical chest wall movement was the cause of the respiratory failure and hypoxia. Now, it is understood that the respiratory impairment is due to the underlying pulmonary parenchymal injury. Historically, efforts were focused on correcting the paradoxical motion through external stabilization (“sandbagging”), and later, “internal pneumatic stabilization” (i.e., positive pressure ventilation).^{43,44} Hence, in the mid-twentieth century, the predominant treatment method for all patients with flail chest was mechanical ventilation. Starting in the mid 1970s, some physicians found that these patients could be adequately managed without ventilatory support. It was at this time that it was recognized that the underlying PC rather than the chest wall instability was the driving factor in outcome.⁴⁵ Currently, less than half of patients with flail chest require mechanical ventilation.⁴⁶ Abnormal gas exchange, not chest wall movement, should drive the decision to mechanically ventilate a patient with flail chest.⁴⁷

In the modern management of flail chest, optimal pain control is paramount. According to the Eastern Association for the Surgery of Trauma practice management guidelines, TEA is the preferred pain treatment modality in the treatment of flail chest.⁴⁸ When an epidural catheter is contraindicated, TPVB may be considered. If mild to moderate respiratory compromise is present, a trial of noninvasive ventilation in conjunction with TEA may be considered before proceeding to endotracheal intubation. However, in the absence of respiratory embarrassment, mechanical ventilation to treat paradoxical chest wall motion is not recommended.

Surgical fixation of the “floating” chest wall segment has been practiced for decades in Europe and Asia, but is underused in the United States, likely due to a combination of relative unfamiliarity with the procedure itself and unfamiliarity with the evidence supporting the procedure. In a survey of trauma surgeons, orthopedic surgeons, and thoracic surgeons, only 26% had ever performed or assisted on the procedure and most were unaware of the published randomized trials supporting its use.⁴⁹ European and Asian studies report clinical benefit, yet the quality of evidence is poor and consists mainly of small, observational single-center studies.⁵⁰⁻⁵² To date, three randomized controlled studies and a meta-analysis evaluating surgical fixation in patients with flail injury have been published supporting rib fracture fixation.⁴³ Tanaka and colleagues reported that patients who underwent internal fixation of their fractured ribs benefited by less mechanical ventilation, lower incidence of pneumonia, shorter ICU LOS, improved pulmonary function, and quicker return to employment.⁵³ Granetzny and coworkers also reported decreased need for mechanical ventilation, shorter ICU LOS, and lower incidence of pneumonia in patients randomized to operation.⁵⁴ Most recently, Marasco and associates demonstrated decreased ICU LOS and decreased need for tracheostomy in patients randomized to operative repair of flail chest, with no difference in duration of invasive mechanical ventilation.⁴⁶ The optimal time for operative intervention is currently unknown and no trial has compared surgical fixation with modern nonoperative management with TEA and chest physiotherapy. An economic analysis based on reported incidences of complications and outcomes concluded that, despite the additional cost of surgery, rib fixation for flail chest remained cost-effective compared with nonoperative management.⁵⁵

Numerous techniques are described for rib fracture fixation, including the use of wire suture, staples, metal or absorbable plates, and screws.¹⁰ A case-control study reported by de Moya and colleagues concluded that rib fracture fixation significantly decreased the need for analgesia.⁵⁶ Infection of rib fixation hardware is uncommon, reported to be approximately 2%.¹⁰

Rescue therapies such as single lung ventilation and high-frequency oscillatory ventilation may be considered when traditional mechanical ventilation fails to improve oxygenation. However, there is no evidence to support routine use of these treatment modalities.

The long-term outcome of flail chest managed nonoperatively is marked by disability, with 70% of patients reporting dyspnea and more than 50% reporting chronic chest wall pain.^{48,57} Less than half of patients are able to return to work.⁵⁸

Sternal Fractures. The most common cause of sternal fracture is motor vehicle crash (eFig. 76-2).⁵⁹ The presence of sternal fractures has traditionally been considered a marker of injury severity, especially in previous decades when seatbelt use was not as widespread. As such, some advocate for hospital admission and close monitoring to rule out other serious injuries, such as blunt cardiac injury. Others report that sternal fracture, ipso facto, is not a significant cause of morbidity or mortality, and many believe that morbidity is mainly attributable to other associated

injuries.⁵⁹⁻⁶² With increasing seatbelt use, the incidence of sternal fractures has increased while mortality has decreased.^{63,64}

In the initial workup of a patient with sternal fracture, it is important to rule out a blunt cardiac injury with a 12-lead electrocardiogram and serum troponin level. Arrhythmias, ST changes, heart block, signs of ischemia, and elevated troponin levels are considered abnormal screening tests and should be followed by a confirmatory echocardiogram; normal findings on electrocardiogram and initial troponin level essentially exclude the diagnosis of blunt cardiac injury.⁶⁵ Nuclear medicine studies are not useful in the diagnostic workup of blunt cardiac injury. As in rib fractures, adequate pain control is paramount in the treatment of sternal fractures. Sternal fracture fixation is rarely indicated.

Clavicle Fractures. The clavicle is an S-shaped bone that acts as a strut between the shoulder and the axial skeleton. It protects the apex of the lung, brachial plexus, and subclavian vessels. Clavicle fractures follow direct impact to the extremity or chest, and account for 44% of all fractures to the shoulder girdle.⁶⁶

Fractures of the middle third are the most common, accounting for 69% to 81% of all clavicular fractures.⁶⁶ Diagnosis of clavicle fractures requires some type of imaging, usually radiography, although many are only visualized on CT. Special radiographic views can be ordered to improve the evaluation for subtle fractures, fracture displacement, or sternoclavicular joint dislocations (eFigs. 76-3 and 76-4). These views include axillary views, 45-degree cephalic tilt, or a serendipity view, which is a 40-degree cephalic tilt.

Treatment generally is nonoperative, with a sling or figure-of-eight brace, and 2 to 6 weeks of immobilization, as well as avoidance of heavy lifting and contact sports for 4 to 6 months. Operative treatment is indicated for all open fractures, skin tenting that will result in an open fracture, and any neurovascular compromise. A recent Cochrane meta-analysis of eight trials involving 555 patients examined the difference between conservative treatment and surgical fixation among patients with fractures of the middle third of the clavicle. Unfortunately, due to heterogeneity between the studies and overall high risk of bias, no strong conclusions can be made and the authors concluded that the decision to operate must be made on a case-by-case basis.⁶⁷

LUNG PARENCHYMA INJURIES

Pulmonary Contusion

PC is a common injury, with an incidence of 30% to 75% in patients suffering blunt thoracic injury⁴⁸ and up to 17% of all trauma admissions. PC is most common after a blunt mechanism of injury, but can also manifest adjacent to a missile tract through lung parenchyma. At the microscopic level, the contused lung displays edema, alveolar and intraparenchymal hemorrhage, and atelectasis, which results in intrapulmonary shunting, ventilation-perfusion mismatch, and decreased lung compliance. This manifests as hypoxemia, hypercarbia, and increased work of breathing. The

full effects of PC may not be obvious immediately; however, clinically significant PC becomes apparent within 24 hours. The natural history of PC is progressive dysfunction over the first few days and resolution within a week.⁶⁸

Severe PC can produce systemic effects. Animal studies demonstrate that after unilateral contusion, there is capillary leak in both ipsilateral and contralateral sides. Both lungs develop increased edema and accumulation of inflammatory cells.⁶⁹ Inflammatory cytokines are increased both locally and systemically, and there is evidence of global immune dysfunction.⁷⁰⁻⁷³ Additionally, PC primes the immune system for an exaggerated response to a subsequent second hit, such as infection^{69,74} (Fig. 76-2). Trauma patients with PC have twice the rate of ventilator-associated pneumonia as those without PC.⁷⁵ At 6 years after injury, more than half of patients with PC have evidence of lung fibrosis on CT scan,⁷⁶ and long-term lung function can be compromised.³⁹

Because not all PCs are clinically significant, several authors have attempted to identify factors predictive of outcome. De Moya and associates developed a simple scoring system, combining the initial CT findings, Glasgow Coma Score, and number of fractured ribs, to predict the need for

Figure 76-2 Inflammatory effects following pulmonary contusion. In the diagram, the potential interactions of the cells and mediators of the innate inflammatory response to contusion are shown. While this inflammatory mechanism may amplify the injury of the contusion, it may also provide potential targets for therapeutic intervention. TLRs, Toll-like receptors. (From Raghavendran K, Notter RH, Davidson BA, et al: Lung contusion: inflammatory mechanisms and interaction with other injuries. *Shock* 32:122–130, 2009.)

mechanical ventilation. Interestingly, in this study, less than one third of all PCs were evident on the initial chest radiograph (eFig. 76-5).⁷⁷ Other authors have questioned the significance of “occult” PC (i.e., apparent only on CT, eFig. 76-6). In a prospective study of 255 patients with PC, Deunk and colleagues reported that patients with occult PC fared no worse than those without PC, while those with PC seen on both chest radiograph and chest CT scan had significantly worse outcomes.⁷⁸ Others have attempted to correlate PC size (as a percentage of total lung volume) with outcomes. Studies have demonstrated that patients with PC volume greater than 20% of total lung volume are at increased risk for requiring mechanical ventilation, developing pneumonia, and developing *acute respiratory distress syndrome* (ARDS).⁷⁹

At this time there is no well-supported intervention to treat PC, and management consists mainly of supportive care and avoidance of iatrogenic injury. Steroids are not recommended and prophylactic antibiotics are strongly discouraged. Four decades ago, Trinkle and coworkers recognized that crystalloid administration increased PC size while diuresis decreased PC size.⁸⁰ Pharmacologic therapies being investigated include arginine vasopressin and dexmedetomidine.⁸¹ A recent animal study reported that dexmedetomidine infusion in a PC model improved hemodynamic parameters, decreased inflammatory infiltration, limited the extent of lung damage, and abrogated pulmonary edema.⁸² In patients with early, severe hypoxemia (arterial $PO_2/FIO_2 < 200$), a trial of noninvasive ventilation may be attempted in order to decrease the need for intubation; however, the development of pneumothorax must be carefully monitored.^{83,84} In animal studies, the application of positive end-expiratory pressure has been shown to decrease the size of PCs. Small clinical studies have reported that recruitment maneuvers are successful in improving aeration (“open lung” strategy).⁸⁵ In patients with PC, the use of airway pressure release ventilation has been reported to decrease the incidence of ventilator-associated pneumonia; however, experience and evidence is limited.⁷⁵ For severe, unilateral PC, lung isolation ventilation may be considered.⁸⁶ The use of rescue therapies such as high-frequency

oscillatory ventilation, surfactant administration, prone positioning, and extracorporeal membrane oxygenation for the treatment of PC is poorly studied and considered experimental at this time.⁸⁷⁻⁹⁰

In the management of PC, the patient should be resuscitated to maintain signs of adequate tissue perfusion. Once this has been achieved, however, meticulous attention should be paid to the avoidance of excessive fluid administration, to the point of using a pulmonary artery catheter if necessary to help guide diuretic therapy.⁴⁸ Aggressive pulmonary toilet and adequate analgesia are paramount in preventing pneumonia.

Pulmonary Laceration

Pulmonary laceration reflects tearing of the pulmonary parenchyma that disrupts the alveolar walls. Pulmonary lacerations result from several mechanisms, such as alternate compression and decompression of the chest wall or from a sudden, rapid increase in intrathoracic pressure with a closed glottis leading to high intra-alveolar pressure that produces shearing of pulmonary parenchymal tissue. Alternatively, pulmonary laceration may also result from direct puncture of lung tissue by a fractured rib, missile, or stab wound, or from shearing of lung tissue fixed by previously formed pleural adhesions. The disrupted pulmonary tissue fills with blood and/or air and manifests on thoracic imaging as one or more pulmonary parenchymal cavities (eFig. 76-7), appearing as gas-fluid levels, frequently with surrounding pulmonary consolidation and ground-glass opacity related to hemorrhage and atelectasis.

While only a small fraction of patients with thoracic injury ultimately require urgent thoracotomy, of those that proceed to surgery, about one third may require lung resection, usually to remove severely injured lung tissue, to control hemorrhage, or to remove irreparable proximal bronchus injuries.⁹¹ The extent of resection can range from simple, nonanatomic “wedge” resection, to formal anatomic lobectomy, to the extremely morbid pneumonectomy. For the majority of penetrating injuries, lung-sparing techniques such as simple suture or “tractotomy” are sufficient⁹¹⁻⁹³ (Fig. 76-3). Not surprisingly, there is a

Figure 76-3 Lung-sparing “tractotomy” in which the tract of the penetrating injury is rapidly opened and injured vessels and bronchi ligated. **A**, The stapling device is advanced through the orifices of the entry and exit wound and is then closed and fired to staple the lung on either side and to open the tract (“tractotomy”) for visualization of the injured vessels and bronchi. **B**, The tractotomy exposes the bleeding vessels, which are then selectively ligated. The tractotomy approach preserves lung by avoiding wedge resection, lobectomy, or pneumonectomy. (From Asensio JA, Demetriades D, Berne JD, et al: Stapled pulmonary tractotomy: a rapid way to control hemorrhage in penetrating pulmonary injuries. *J Am Coll Surg* 185:486–487, 1977.)

stepwise increase in mortality with increasing extent of lung resection for trauma: wedge resection (19%), lobectomy (27%), and pneumonectomy (53%).

While most healthy patients can tolerate a wedge resection or lobectomy, pneumonectomy imposes a tremendous physiologic burden and patients may succumb to right ventricular failure. Using a porcine model, Cryer and colleagues demonstrated that pulmonary vascular resistance increases up to 500% within 4 hours after pneumonectomy.⁹⁴ Postoperative complications in survivors are common, and include pneumonia, bronchopleural fistula, empyema, or erosion into the pulmonary artery.

Bronchopleural Fistula

A bronchopleural fistula is a direct connection between the bronchus and atmosphere by way of the pleural space and tube thoracostomy. While most heal spontaneously, a persistent bronchopleural fistula may seriously impair the ability to ventilate a patient secondary to loss of tidal volume through the fistula. It is believed that air flowing through the fistula impedes healing and therefore medical therapies are aimed at reducing bronchopleural fistula flow.

Nonsurgical treatments include minimizing airway pressures (via lower tidal volumes, positive end-expiratory pressure, and inspiratory time), application of positive intrapleural pressure through the chest tube, isolated contralateral lung ventilation, dependent positioning of the side with the bronchopleural fistula, and use of high-frequency oscillatory ventilation.⁹⁵⁻⁹⁷ Bronchoscopy is useful to identify the injury directly (proximal) or the affected bronchial segment (distal). A balloon is used to occlude the segments sequentially until a reduction in air leak is noted. Once the affected bronchus is identified, agents such as silver nitrate, cyanoacrylate-based agents, gelatin, fibrin, and even fishing weights have been applied to occlude the bronchial segment and close the fistula.⁹⁸⁻¹⁰² Bronchopleural fistula refractory to medical therapy for more than 7 days may require pleurodesis or operative intervention.

Miscellaneous

Pneumothorax. Pneumothorax, air within the pleural cavity, is present in 40% and 20% of blunt and penetrating thoracic trauma patients, respectively (see Chapter 81).¹⁰³ The clinical consequence of pneumothorax ranges from asymptomatic to the most life-threatening manifestation, “tension” pneumothorax, whereby progressive air trapping in the thorax results in a contralateral mediastinal shift, compression or kinking of the superior vena cava/inferior vena cava, and a precipitous drop in preload and cardiac output (Fig. 76-4). Clinically, this form of “obstructive” shock manifests as hypotension and hypoxia, and should be treated with immediate thoracic decompression, either with needle thoracostomy or tube thoracostomy. Current recommendations from the Advanced Trauma Life Support program¹⁰⁴ are to insert the needle in the mid-clavicular line at the second intercostal space; however, some authors have questioned the efficacy of inserting the needle in this location and recommend instead inserting the needle in the mid-axillary line at the fifth intercostal space because of decreased chest wall thickness in this location.¹⁰⁵ Additionally, lateral needle insertion avoids potentially life-threatening hemorrhagic complications such as laceration

Figure 76-4 Tension pneumothorax. The free air in the left hemithorax is associated with a shift of the mediastinum into the right chest, depression of the hemidiaphragm, and widening of the intercostal spaces. Hypotension follows due to impairment of venous return to the right heart, both by the high intrathoracic pressure and perhaps mechanical compression or kinking of the superior vena cava. Immediate decompression is required.

of the internal mammary artery, subclavian artery, or pulmonary artery.^{106,107} Others recommend inserting a chest tube at the outset instead of a needle due to frequent failure rates associated with the latter.¹⁰⁸

An open pneumothorax, or “sucking” chest wound, is a special form of pneumothorax whereby a defect in the chest wall permits air entry through the wound with diaphragmatic movement. If the size of the wound approaches the size of the trachea, this may significantly hamper ventilation, because air preferentially enters through the wound.¹⁰⁹ Before operative repair, the wound should be covered with a flutter (“Heimlich”) valve or an occlusive dressing with one side open to allow air egress.

For less severe pneumothorax, the decision to drain the pleural cavity should be made based on the degree of respiratory compromise and the potential for enlargement to a tension pneumothorax. Managed without tube thoracostomy, it is estimated that the average pneumothorax absorption rate is 1.25% per day.¹¹⁰ Clinical significance of a pneumothorax depends not only upon the absolute size of the pneumothorax, but also on the preinjury condition of the patient (e.g., presence of chronic obstructive pulmonary disease) and other associated injuries. Chest tube insertion is not without risk, and modern series report a 15% to 20% incidence of tube-related complications, with an additional 15% requiring more chest tubes after suboptimal placement^{111,112} (Fig. 76-5). One rare but potentially fatal complication following pneumothorax drainage is reexpansion pulmonary edema¹¹³ (Fig. 76-6). Prophylactic antibiotics for the duration of dwell time of the chest tube are not recommended.¹¹⁴

An “occult” pneumothorax is defined as a pneumothorax which can only be visualized on chest CT scan; it is not

Figure 76-5 Tube thoracostomy placement. Diagram showing the placement of a thoracostomy tube in the mid-axillary line; the tube is directed anteriorly for drainage of a pneumothorax. (From Van Way CW III, Buerk CA: Surgical skills in patient care. St. Louis, 1978, CV Mosby.)

detectable on chest x-ray nor is it suspected on clinical examination (Fig. 76-7). “Occult” pneumothorax is present in up to 12% of seriously injured patients^{115,116} and, in an era of liberal CT scanning, comprise more than 50% of all pneumothoraces diagnosed in injured patients.¹¹⁷ Supine portable chest radiographs have been consistently shown to be only 50% sensitive for the detection of pneumothorax. Ultrasonography has been shown to be more sensitive than chest radiography for the detection of pneumothorax.¹¹⁸⁻¹²⁷ Subtle findings on supine chest radiograph suggestive of pneumothorax include the “deep sulcus” sign (Fig. 76-8).

The management of “occult” pneumothorax has evolved over the past 3 decades from mandatory tube thoracostomy for all “occult” pneumothoraces, progressing to selective drainage for only those patients undergoing positive pressure ventilation,¹²⁸ to selective drainage for all patients.^{115,128} In a large, multicenter observational study involving 569 patients with “occult” pneumothorax across 16 trauma

Figure 76-6 Reexpansion pulmonary edema. **A**, A pneumothorax can be seen on the right with a subtotal lung collapse. **B**, The same patient after expansion of the lung following placement of a thoracostomy tube. Peripheral right upper lobe opacity is now present, consistent with the development of reexpansion injury and edema in that region of lung. (From Malota M, Kowarik MC, Bechtold B, Kopp R: Reexpansion pulmonary edema following a post-traumatic pneumothorax: a case report and review of the literature. *World J Emerg Surg* 6:32, 2011.)

There is no obvious pneumothorax. **B**, CT scan reveals a large occult left-sided pneumothorax. (From Ball CG, Hameed SM, Evans D, et al: Occult pneumothorax in the mechanically ventilated trauma patient. *Can J Surg* 46:373–379, 2003.)

Figure 76-8 Deep sulcus sign on chest radiograph. In this supine patient, a pneumothorax on the left can be recognized by the depth of the diaphragmatic sulcus on the left compared with the right (arrows). There is also lucency overlying the left hemidiaphragm, representing air anterior and lateral to the left hemidiaphragm and seen as an air-tissue interface (arrowheads).

centers, Moore and colleagues reported that 21% required immediate tube thoracostomy. Of the remaining patients, however, only 6% overall failed observation and required tube thoracostomy for pneumothorax enlargement, respiratory distress, or development of hemothorax. In this series, 14% of patients on positive pressure ventilation required tube thoracostomy. Importantly, no patient who failed observation experienced an adverse event resulting from delay of chest drainage.¹²⁹

After drainage, standard management of the chest tube entails serial chest radiographs to document resolution of the pneumothorax. A bedside clinical examination should be performed to rule out an ongoing air leak, which is usually secondary to persistent alveolar-pleural fistula.¹³⁰ Air leaks may be graded according to increasing severity: forced expiratory, expiratory, inspiratory, and continuous. The vast majority of posttraumatic air leaks in stable patients are forced expiratory (coughing) or expiratory and almost all resolve with time and patience.¹³⁰ Typically, the chest tube is placed at 20 cm H₂O suction and “advanced” to water seal before removal. It is customary to obtain a chest radiograph after transitioning to water seal and after chest tube removal to monitor for pneumothorax reappearance. Pneumothorax recurs after chest tube removal in 11% to 24% of cases; however, if the pneumothorax is small and stable and the patient is asymptomatic, observation is frequently successful.^{131,132} It is common practice to allow up to 24 hours between changes in chest tube management, however Schulman and associates reported that

changes may be made at shorter intervals, because clinically significant recurrent pneumothorax appeared within 3 hours.¹³³

Accumulating evidence suggests that smaller 14- to 16-French “pigtail” catheters are equally effective as traditional large-bore chest tubes (28- to 40-French), require less dissection, can be placed by the Seldinger technique, and may be less painful.^{134,135}

Hemothorax. A hemothorax is blood in the pleural cavity that can cause a wide range of symptoms from minor discomfort to life-threatening situations (eFig. 76-8). In general, hemothorax evident on supine chest radiograph should be drained immediately, because these typically represent volumes of at least 200 mL. Similar to “occult” pneumothorax, “occult” hemothoraces also exist and the decision to drain an “occult” hemothorax should take into consideration the amount of blood present and the morbidity of chest tube insertion.

The initial treatment of hemothorax is tube thoracostomy. Based on the volume of initial output, the next step may be either urgent thoracotomy or observation. If the source of bleeding is the pulmonary parenchyma, hemostasis is usually achieved by complete expansion of the lung because the pulmonary circulation is a low pressure circuit. Bleeding from lacerated intercostal or internal mammary arteries is likely to persist and may require urgent thoracotomy for definitive hemostasis. Indications for urgent thoracotomy include hemodynamic instability, 1500 mL initial chest tube output, greater than 1500 mL over a 24-hour period, or greater than 200 mL/hr blood drainage for 3 consecutive hours.¹³⁶ Hemothorax secondary to major thoracic vascular structures (e.g., aorta, pulmonary artery) almost universally requires emergent thoracotomy for hemodynamic instability.

Assuming adequate drainage and resolution of the hemothorax, it is customary to “advance” the chest tube to water seal before removal, similar to the chest tube management for a simple pneumothorax (see earlier). An additional factor to consider is the daily volume of bloody chest tube drainage. While there are no standardized guidelines or recommendations, the majority of trauma surgeons advance a chest tube once the daily output decreases to between 100 mL and 300 mL per day.

The evacuation of a hemothorax can be incomplete in up to 20% of cases and can be frustrating to deal with.^{132,137,138} Untreated, a stagnant hemothorax may evolve into empyema or fibrothorax (“trapped lung”), two morbid complications.¹³⁹ Additional chest tube placement is usually ineffective for clot evacuation.

Early *video-assisted thoracic surgery* (VATS) (less than 5 days after injury), compared with delayed operation or additional chest tubes, has been reported to decrease hospital LOS and decrease conversion to open thoracotomy.^{140,141} According to the Eastern Association for the Surgery of Trauma guidelines, there is level 1 evidence that a retained hemothorax should be treated with early VATS, and not insertion of a second chest tube. VATS should be considered within 3 to 7 days of hospitalization because this reduces the risk for infection and the requirement for thoracotomy (level 2 evidence). Retained hemothorax less than 300 mL by chest CT scan may be observed.¹⁴² Currently, intrapleural

Figure 76-9 Comparison of fluid dynamics between two different sizes of pleural drains. The smaller drain (19-French, blue) is as effective as the larger one (28-French, brown) in draining fluid. (From Niinami H, Tabata M, Takeuchi Y, Umezumi M: Experimental assessment of the drainage capacity of small silastic chest drains. *Asian Cardiovasc Thorac Ann* 14:223–226, 2006.)

thrombolytics are considered second line treatment after VATS and can be considered in subacute hemothoraces to improve drainage.^{143,144}

Over the past decade, there has been a trend toward using smaller chest tubes for evacuating hemothorax.¹³⁵ When comparing the standard 36-French to 40-French chest tube with 28-French to 32-French tubes, Inaba and colleagues found that the initial drainage volume and total indwelling time were similar and there were no differences between groups in tube-related complications or the need for additional interventions.¹⁴⁵ A recent animal study of flow dynamics provides even further evidence to support that smaller tube size is equally effective for hemothorax evacuation. Niinami and coworkers reported that a 19-French fluted silicone drain is capable of draining 11 L/hour¹⁴⁶ (Fig. 76-9). Similarly, Kulvatunyou and colleagues reported that a 14-French “pigtail” catheter seems to drain blood as effectively as larger bore traditional chest tubes, with a similar incidence of complications.¹⁴⁷

Chylothorax. Traumatic chylothorax is an uncommon entity that results from disruption of the thoracic duct. Chylothorax presents as a milky pleural effusion upon resumption of oral intake and the diagnosis is confirmed by finding triglyceride levels greater than 110 mg/dL with or without lymphocytes predominating.¹⁴⁸ Initial treatment involves lung reexpansion and parenteral nutrition, with the possible addition of octreotide. If these measures fail, thoracic duct embolization or operative intervention is warranted.¹⁴⁹ However, the optimal duration of nonoperative management is unknown.

Pneumatocele/Intraparenchymal Hematoma. Also termed a *posttraumatic pulmonary pseudocyst*, a pneumatocele is an atraumatic cavitory lesion within the parenchyma following a pulmonary laceration (eFig. 76-9). Asymptomatic patients may be managed expectantly and most resolve within several weeks. For infectious complications, antibiotic

ics and CT-guided catheter drainage may be attempted. Operative resection (VATS or thoracotomy) may be necessary if less invasive measures fail.

TRACHEOBRONCHIAL INJURIES

Tracheobronchial injuries present in one of two ways, depending upon site, size, and communication with the pleural cavity: they are either immediately apparent, requiring immediate attention (11%), or they are very subtle and difficult to diagnose.^{150,151} Two thirds are unrecognized for more than 24 hours and, in 10%, there is no evidence of thoracic injury on physical examination or radiographs.¹⁵⁰ In this second group of patients, there is no discernible morbidity associated with delayed repair. Death is usually not from the tracheobronchial injury itself, but instead from fatal injuries to adjacent vascular structures.¹⁵² Even with complete transection, the robust peritracheal connective tissue can splint the tracheal fragments, maintaining airway continuity. Blunt force likely injures the tracheobronchial tree by one of three mechanisms: rupture from tracheal compression against the rigid vertebral column, rupture from increased airway pressures due to compression of the chest with a closed glottis, or laceration from shearing forces.¹⁵³

The majority of tracheobronchial injuries take place within 2.5 cm of the carina, with main stem bronchial injuries comprising the majority (86%).^{150,153} Clinically, the patient may have dyspnea (the most common symptom), hoarseness, stridor, hemoptysis, crepitus, or respiratory distress. Radiographically, the “fallen lung” sign, first described by Oh and associates in 1969, is a highly specific finding for this injury. This sign manifests when the patient has a pneumothorax. When pneumothorax is present without tracheobronchial injury, the lung falls *toward* the hilum (central displacement), whereas with tracheobronchial injury, the transected lung falls *away* from the hilum (peripheral displacement) (Fig. 76-10). CT scanning may demonstrate bronchial wall discontinuity (eFig. 76-10 and Video 76-3) or mediastinal emphysema. A tracheal or proximal bronchus injury should be suspected with pneumomediastinum or with a pneumothorax refractory to chest drainage. Bronchoscopy is the most effective method of diagnosis.

Although the treatment for large or life-threatening tracheobronchial injuries is immediate repair, selective intubation beyond the injury alone (or even observation alone) may be successful in carefully selected patients with small or partial thickness injuries.^{7,154}

Delayed complications of unrecognized injury include bronchopleural fistula, atelectasis, bronchiectasis, and postobstructive pneumonia as well as more serious sequelae such as mediastinitis or cervical abscess.

DIAPHRAGM INJURIES

Diaphragmatic injury is a rare but morbid injury, presenting in less than 1% of blunt trauma and associated with a 21% overall mortality rate.¹⁵⁵ More than 90% are seen after motor vehicle crashes. Two thirds of diaphragm injuries develop on the left, perhaps because the liver cushions the impact on the right side. Because of the significant force

required to rupture the diaphragm, these injuries are almost universally accompanied by other organ injuries, such as lung (77%), liver (52%), spleen (32%), and stomach (19%).¹⁵⁵

The physical examination is inaccurate for the diagnosis of diaphragmatic injuries. For most victims of penetrating injury, there is no sign unique to diaphragmatic injury. For patients following blunt trauma, dyspnea and pain are common but nonspecific. Chest radiography is diagnostic in fewer than half of those with injury to the left hemidiaphragm (eFig. 76-11) and in only 17% of those with injury

Figure 76-10 “Fallen lung” sign. Chest radiograph obtained 6 hours after initial presentation of acute dyspnea in an 8-year-old boy. Bilateral pneumothorax, more prominent on the right, is seen. Pneumomediastinum and soft tissue emphysema are observed. The right lung is seen to be collapsed inferior to the hilum (fallen lung sign), usually a sign of complete rupture of the main bronchus. A thoracostomy tube has been inserted on the right, yet a large right pneumothorax remains. (From Savas R, Alper H: Fallen lung sign: radiographic findings. *Diagn Interv Radiol* 14:120–121, 2008.)

to the right hemidiaphragm¹⁵⁶ (Fig. 76-11). CT scan has a very high sensitivity for blunt diaphragmatic rupture. Imaging signs of injury include: a nasogastric tube terminating above the diaphragmatic contour, discontinuity of the hemidiaphragm, herniation of the viscera into the thorax (eFig. 76-12), diaphragmatic thickening (eFig. 76-13), the “hump sign,” the “band sign,” the “dependent viscera sign” (eFig. 76-14), the “collar sign” (eFig. 76-15), and the “dangling sign.”^{157,158}

All acute diaphragmatic injuries should be surgically repaired. The natural history of traumatic diaphragmatic hernias is poorly studied, but it is presumed that the tendency is to enlarge over time, with progressive herniation of abdominal viscera into the chest due to the negative intrathoracic pressure and positive intra-abdominal pressure. For left-sided penetrating thoracoabdominal wounds, if there is no immediate indication for operative exploration, it is recommended to perform a diagnostic laparoscopy, because 20% will have diaphragm injuries.^{159,160}

BLAST LUNG INJURY

INTRODUCTION

An increasing frequency of terrorist bombing attacks worldwide has resulted in a large number of civilian blast injuries.¹⁶¹ Blast victims require a standard trauma workup as recommended by Advanced Trauma Life Support. Additionally, such victims may also present with a set of pulmonary injuries unique to the blast mechanism.¹⁶²

Victims of blast injuries manifest different injuries depending on the type of the bomb, the location of detonation, and whether the targets were military or civilian. Typically, military victims have different injuries from civilian victims. Military personnel are young and healthy, and usually have body armor that protects their thoracic and abdominal organs, whereas civilian victims range from children to older adults and are not wearing body protection. Thus civilian victims present with more thoracic/lung

Figure 76-11 Hemidiaphragmatic injury in the setting of trauma. A, Right hemidiaphragmatic injury. Frontal chest radiograph shows apparent elevation of the right hemidiaphragm, generally a nonspecific finding. However, in the setting of trauma, diaphragmatic injury with herniation of the liver into the thorax manifests similarly, as in this example. B, Left hemidiaphragmatic injury. Frontal chest radiograph shows herniation of the stomach into the left thorax, consistent with a large tear of the left hemidiaphragm.

and abdominal injuries than military victims. As a general rule, blast injury victims suffer multiple blunt and penetrating injuries, including traumatic amputations. Injuries from blast detonations are classified into the following categories: (1) primary; (2) secondary; (3) tertiary; and (4) quaternary.¹⁶²

PRIMARY BLAST INJURIES

Primary blast injuries result from overpressure effects of the blast wave (see later). The blast typically injures organs that have interfaces between different densities, such as air and tissue, or water and air. Examples include pulmonary barotrauma, tympanic membrane ruptures, gastrointestinal contusions/perforations, and traumatic amputations. Previously, tympanic membrane rupture was used as a marker of severity of illness from the blast wave. However, recent studies show that tympanic membrane rupture is not a reliable marker of severity, demonstrating poor sensitivity and specificity.¹⁶³ Instead, markers of severe blast injury include the following: (1) >10% total body surface area burns; (2) skull/facial fractures; (3) penetrating injuries to the head/torso.¹⁶³

SECONDARY BLAST INJURIES

Secondary blast injuries result when penetrating injuries are caused by flying debris, such as bomb fragments from the explosive device and fragments of bone and teeth from the bomber and victims. There are case reports of these biologic fragments transmitting hepatitis B.^{164,165} Theoretically, transmission of hepatitis C and HIV are also possible.

TERTIARY BLAST INJURIES

Tertiary blast injuries result when victims are physically propelled into hard surfaces by the force of the blast wave. Crush injuries from falling debris also fit into this category.

QUATERNARY BLAST INJURIES

Quaternary blast injuries encompass all other explosion-related effects such as burns, asphyxia, radiation poisoning, toxins, psychological trauma, and exacerbation of underlying medical conditions.

PHYSICS OF THE BLAST WAVE

Explosions result when a chemical reaction transforms a solid or liquid into gas within a very short time period, resulting in a massive release of energy. The explosion releases most of its energy as a “blast wave,” a positive pressure front that travels faster than the speed of sound.¹⁶⁶ As a result, victims feel the blast wave before hearing the explosion. In the open-air, the blast wave behaves in a predictable manner based on the physics of wave motion.¹⁶⁷

Detonations within confined spaces or under water cause blast waves that are accentuated and deadlier.^{162,164} Under these conditions, blast waves are reflected back from surfaces with a different density, such as walls or air-water interfaces. The reflected wave superimposes and amplifies the outgoing blast wave, causing a higher intensity and

thus much deadlier blast wave. Furthermore, the blast wave can reflect back from surfaces at an angle greater than 40 degrees, augmenting the incoming wave and creating a new blast wave. This phenomenon is known as a “mach stem formation.”¹⁶⁸ Studies have shown that explosions detonated in corners can result in explosions that are up to eight times deadlier than explosions in the open air.¹⁶⁴

Damage to the human body results when the blast wave transmits energy directly to the body. This energy is transmitted unevenly through body tissues and, as described, reflects back upon encountering changes in density. As a result, the majority of damage is done at interfaces of different tissue densities. For example, pulmonary blast injuries result when the blast wave rapidly changes in amplitude upon entering and exiting the multiple air- and fluid-filled structures within the lungs. Other air/tissue interfaces include the gastrointestinal tract, tympanic membranes, and extremities, where greatly disparate density planes, such as joints with air, soft tissue, and bones all reside within a small space. The mechanisms causing these injuries can be classified physiologically into distinct categories: (1) spalling forces, (2) implosion forces, and (3) inertia forces.^{162,167}

Spalling Forces

Spalling forces result when the blast wave displaces and fragments one tissue into another tissue, usually the higher density tissue into the lower density tissue. For example, spalling forces cause the forcible movement of blood from the capillaries into the alveoli, causing alveolar hemorrhage.

Implosion Forces

Implosion forces result when the highly compressed edge of the blast wave enters the victim. This results in gas that rapidly compresses and reexpands causing injury. For example, implosion forces cause barotrauma by compressing and reexpanding the air in the alveoli. Furthermore, this rapid change in air density can cause an air embolism by entering the circulatory system.

Inertia Forces

Inertia forces result when the blast wave causes the different tissue densities to absorb different amounts of energy. This results in the different tissues moving at different velocities. The resulting shearing of tissue planes causes massive injuries, typically traumatic avulsions/amputations.

Blast lung injury results from the combination of all the forces described above. After the initial damage to the architecture of the alveoli, pulmonary hemorrhage ensues. The free hemoglobin in the alveoli leads to the formation of free radicals, worsening edema and an early inflammatory response.^{169,170} This leukocyte accumulation and release of inflammatory cytokines leads to further epithelial cell damage over 12 to 24 hours, as well as endothelial cell damage over 24 to 56 hours. This inflammatory cascade results in a lung injury syndrome characteristic of ARDS.

Histologic examination of the lung damaged by blast injury reveals perivascular edema, extensive alveolar hemorrhage during the first 12 hours, and then further epithelial cell damage and detachment from the basement membrane.^{169,170}

MANAGEMENT OF BLAST LUNG INJURY

Initial management of patients with blast lung injury should follow standard local trauma protocols and Advanced Trauma Life Support teaching. Survivors of the blast wave with primary blast lung injury have a mortality rate of 11% and represent a group of patients with very severe injuries.

Clinical features include shortness of breath, cough, chest pain, hemoptysis, cyanosis, and tachypnea. Hypoxemia is a typical finding, but may not develop until after the first few hours following presentation. One case series found that only 28% of patients had hypoxemia on initial presentation.¹⁷⁰

All patients with suspected blast lung injury should receive a chest radiograph as soon as possible. Radiographic findings of blast injury may include not only the classic “bat wing” appearance on chest radiograph but also subcutaneous emphysema; pneumothorax; pulmonary interstitial emphysema; pneumopericardium; pneumomediastinum; and pneumoperitoneum.

The general treatment for primary blast lung injury patients is similar to the treatment for the ARDS patient. This includes limiting fluid administration to decrease the chance of pulmonary edema and the use of low-tidal-volume “lung-protective” ventilation with permissive hypercapnia to minimize peak and plateau airway pressures.¹⁷¹ Refractory cases can be considered for rescue treatments for ARDS, such as inhaled nitric oxide, inhaled prostaglandins, and open-lung ventilation strategies. However, caution should be used when considering extracorporeal membrane oxygenation. The underlying pathophysiology of blast lung involves alveolar hemorrhage and, as a result, there are reports that the required anticoagulation for extracorporeal membrane oxygenation results in catastrophic pulmonary hemorrhage.¹⁷²

In the rare case of air embolism from the blast lung injury, treatment aims to prevent further air emboli. The patient is placed in the left lateral decubitus position, with the head down and feet up in an attempt to contain the air embolism at the apex of the left ventricle. Peak pressures during positive-pressure ventilation should be minimized and hyperbaric therapy considered. The diagnosis is a clinical one because CT scans, echocardiography, and observation of retinal air bubbles on fundoscopic exams are unreliable.¹⁶²

Patients that survive blast lung injury typically have excellent long-term pulmonary outcomes. One study found that, one year after the injury, survivors had normal pulmonary exams, with minimal pulmonary complications.¹⁷³

INITIAL MANAGEMENT AND DIAGNOSTIC APPROACH TO THE THORACIC TRAUMA PATIENT

The assessment of every trauma patient begins with the time-honored “ABCs”—airway, breathing, and circulation. In case of suspected tension pneumothorax, pleural decompression should precede intubation. A complete physical exam should follow the ABCs, with special attention paid to the presence of decreased breath sounds, distended neck veins, subcutaneous emphysema, and upper extremity pulse or neurologic deficits.

If there is a concern for thoracic injury and the patient has stable vital signs, workup can begin with a chest radiograph and thoracic ultrasound. The ultrasound should be considered as an extension of the physical examination, and a careful survey of the pericardium and bilateral thoracic cavities should be performed on every patient. Large or clinically significant pneumothoraces or hemothoraces should be treated immediately with tube thoracostomy prior to leaving the trauma bay of the emergency department. Depending upon the chest radiograph and ultrasound findings, a chest CT scan or bronchoscopy may be required to delineate injury further.

Key Points

- The majority of patients with pneumothorax and hemothorax may be adequately managed by tube thoracostomy alone.
- The cornerstone of treatment for rib fractures and flail chest is pain control.
- Pulmonary contusion is a major driver of morbidity and can cause systemic immune dysfunction.
- Occult pneumothorax may be safely managed with observation, even in patients on positive pressure ventilation.
- Blast lung injury is a unique form of lung injury, which is most commonly seen in survivors of closed-space explosions.
- The diagnosis of blast lung injury is based on clinical observations and confirmed by plain chest radiograph. Lung injury is the leading cause of late blast mortality.
- Management of blast lung injury is predominantly supportive and closely approximates the treatment of acute respiratory distress syndrome.

INTRODUCTION

Nearly 100 million people live at altitudes greater than 2500 m, primarily in the Rocky Mountains of North America, the Andes Mountains of South America, the Ethiopian Highlands of East Africa, and the Himalaya Mountains of South-Central Asia. These people have developed the ability to live and reproduce at elevations as high as 5000 m, but in some cases, develop chronic medical problems attributable to their high-altitude residence. In addition to long-term residents, many lowlanders venture to high altitude for work and recreation. These more acute exposures also pose the hazards of acute altitude illnesses or altitude-related exacerbations of preexisting diseases. With growing awareness of such risks, persons are seeking advice on traveling to these regions. It is, therefore, imperative that the counseling physician be able to provide guidance about minimizing risks and managing problems.

This chapter reviews the normal adaptive processes that take place in response to high altitude, specifically the compensatory changes in the transport of oxygen from the air to the tissues in the setting of decreased barometric pressure. Acute and chronic adaptation are discussed, and factors determining the limits of adaptation and performance at high altitude are explored. Also reviewed are the consequences of maladaptation—the acute and chronic illnesses of high altitude—and strategies for managing these situations are discussed. Finally, an approach to the traveler with underlying medical problems who is planning a trip to high altitude is presented.

ADAPTATION TO HIGH ALTITUDE

The *partial pressure of oxygen* (PO_2) diminishes as oxygen moves from air to the tissues. Ventilation, regional matching of ventilation and blood flow, diffusion of oxygen from air to the blood, transport within the circulation, diffusion of oxygen from blood into the tissue, and metabolism in the mitochondria are all links in this oxygen transport chain. As altitude increases, the barometric pressure declines (Table 77-1); as a result, PO_2 at every step in this chain is lower than it would be at sea level. Compensatory processes take place at each step in the chain at different rates to raise

PO_2 and maintain adequate oxygen delivery, thereby facilitating tolerance of the hypoxic environment.

The process of adaptation is vitally important to survival at high altitude. Whereas a person who makes a sudden ascent from sea level to the summit of Mt. Everest (8848 m) by helicopter, for example, would become unconscious within minutes and die soon thereafter, a climber using an appropriately slow ascent rate can complete the climb without obvious effects because of the body's adaption to the hypoxic environment. Since the latter half of the nineteenth century, researchers have investigated the full spectrum of these adaptive responses, creating a vast literature that has been reviewed extensively by Swenson and Bartsch¹ and West and colleagues.² A summary of the key features of the adaptive responses to high altitude follows.

PULMONARY ADAPTATION**Control of Ventilation**

Acute Response. Upon acute exposure to hypoxia, alveolar ventilation increases. This response, the *hypoxic ventilatory response* (HVR), minimizes the drop in alveolar PO_2 (Fig. 77-1). Individuals vary in this response, which subsequently plays an important role in adaptation, maladaptation, and performance at high altitude. Large increases in ventilation are generally not seen until the arterial PO_2 falls below 60 mm Hg and, at any given altitude, ventilation continues to increase over weeks, in a process called *ventilatory acclimatization*. At extreme elevations, the increase in minute ventilation can be dramatic, representing a large metabolic cost. Data obtained from several individuals just below the summit of Mt. Everest (at 8400 m, barometric pressure approximately 272 mm Hg) revealed an average arterial PCO_2 of 13 mm Hg. As a result, despite an inspired PO_2 of only 47 mm Hg, the mean arterial PO_2 was maintained at roughly 30 mm Hg.³

The HVR is mediated by peripheral chemoreceptors in the carotid body. Neural discharge from the whole carotid sinus nerve is related hyperbolically to decreasing arterial PO_2 ,⁴ and surgical ablation of carotid body input (e.g., carotid endarterectomy or bilateral carotid body resection for intractable dyspnea) results in loss of the ventilatory response to acute hypoxia.⁵

Table 77-1 U.S. Standard Atmosphere: Altitude, Barometric Pressure, and Inspired Partial Pressure of Oxygen*

Altitude (meters)	Altitude (feet)	Barometric Pressure (mm Hg)	Inspired PO ₂ (mm Hg)
0	0	760	159
1000	3280	674	141
2000	6560	596	125
3000	9840	526	110
4000	13,120	463	97
5000	16,400	405	85
6000	19,680	354	79
8000	26,240	268	56
8848	29,028	253	43

*Values except 8848 m, are taken for mid-latitude (45°N). There is greater variation at higher latitudes.

Figure 77-1 Oxygen-carbon dioxide diagram demonstrating the alveolar gas composition in acclimatized subjects at high altitude. Solid circles represent data collected by Rahn and Otis (Rahn H, Otis AB: Man's respiratory response during and after acclimatization to high altitude. *Am J Physiol* 157:445–449, 1949), while the triangles are measurements from three altitudes on Mt. Everest. At extreme altitudes, marked hyperventilation maintains alveolar PO₂ at approximately 35 mm Hg. (From West JB, Hackett PH, Maret KH, et al: Pulmonary gas exchange on the summit of Mt. Everest. *J Appl Physiol* 55:678–687, 1983.)

In response to a relatively constant hypoxic stimulus, ventilation increases over time (Fig. 77-2). With initial exposure and the subsequent acute rise in minute ventilation, arterial PCO₂ at the medullary and peripheral chemosensors decreases and depresses the ventilatory response.⁶ Subsequently, over days, ventilation increases and continues to rise for months.⁷ The classic explanation for this ongoing increase was that the slower renal compensation for the respiratory alkalosis permitted near full realization of the hypoxic stimulus to ventilation. However, blood pH reveals that hypocapnic alkalemia persists as ventilation increases, suggesting that other mechanisms beyond renal compensation, which is completed within 3 to 4 days, must be responsible for this change. It was proposed that a rela-

Figure 77-2 Ventilatory acclimatization during 10- to 11-day sojourn to 4300 m. Ventilation continues to increase as cerebrospinal fluid acid-base alterations parallel plasma changes. HCO₃⁻, bicarbonate; PaO₂, arterial oxygen tension; PCO₂, carbon dioxide tension; V_E, minute volume of ventilation. (From Forster HV, Dempsey JA, Chosy LW: Incomplete compensation of CSF [H⁺] in man during acclimatization to high altitude [4300 m]. *J Appl Physiol* 38:1067–1072, 1975.)

tive acidosis in the *cerebrospinal fluid* (CSF) and at medullary chemosensors triggers the increased ventilation but lumbar CSF remains alkaline during high-altitude (3100 m) sojourns of up to 3 weeks, while during deacclimatization, hyperventilation persists even when arterial PCO₂ and blood and CSF pH have returned toward normal.⁸ The pH of brain interstitial and intracellular fluid has also failed to show changes that could account for the increase in ventilation.⁹ These results suggest that some mediator other than hydrogen ion sustains the hyperventilation during a high-altitude sojourn. One possible mediator may be erythropoietin signaling in the brain via erythropoietin receptors.¹⁰ Another factor that would promote progressive hyperventilation is an increase over time in carotid body sensitivity to hypoxia.¹¹

Intermittent Hypoxic Exposure. The sustained increase in ventilation generally pertains to exposures lasting days to weeks. Shorter intermittent exposures also affect ventilatory responses to both oxygen and carbon dioxide.¹² Studies have focused on the “dose” and frequency of the hypoxic stimulus necessary to induce a physiologic response. For example, 8 hours of exposure to isocapnic and poikilocapnic

(i.e., varying PCO_2) hypoxia (end-tidal $PO_2 = 55$ mm Hg) increases the chemosensitivity to carbon dioxide compared to controls,¹³ while a 1 hr/day exposure to a simulated 4500-m altitude was associated with increased HVR, ventilatory equivalents (\dot{V}_E/\dot{V}_{O_2}), and arterial SO_2 during post-exposure hypoxia.¹⁴

Chronic Ventilatory Adaptation. Long-term high-altitude residents have lower ventilation and higher arterial PCO_2 than acclimatized lowlanders at the same elevation and have blunted ventilatory responses to acute hypoxia.¹⁵ The blunted response arises in conjunction with carotid body hypertrophy and may be an adaptive phenomenon in which the disadvantage of the lower arterial PO_2 is offset by the decreased work of breathing associated with lower ventilation.

Pulmonary Function and Mechanics

On ascent, lung function changes in several ways. Vital capacity decreases in the first 24 hours and remains depressed at high altitude.¹⁶ Proposed mechanisms for a lower vital capacity include increased interstitial fluid volume, resulting in airway narrowing, gas trapping, and delayed emptying of some lung units,¹⁶ pulmonary vascular engorgement,¹⁷ decreased respiratory muscle strength,¹⁸ and reduction in lung compliance by hypocapnia.¹⁹ In addition, peak expiratory flow rates are increased and airway resistance is reduced.²⁰ The lower airway resistance is presumably due to decreased air density, which counteracts any narrowing of airways due to hypoxia and hypocapnia.

In contrast, vital capacity is increased in high-altitude residents compared to that in nonnative residents,²¹ with the magnitude of the increase dependent on the length of stay at high altitude. Those born and raised at high altitude develop larger vital capacities than those who move to high altitude later in life.²²

Gas Exchange

Ventilation and Perfusion Matching. The increase in ventilation during acute hypoxia is matched by increased cardiac output and pulmonary perfusion. Additionally, alveolar hypoxia triggers *hypoxic pulmonary vasoconstriction* (HPV), which increases pulmonary vascular resistance. These changes cause redistribution of blood flow to areas of the lung that are usually less well perfused at sea level and may, thereby, improve \dot{V}_A/\dot{Q} matching and optimize gas exchange.

Diffusion. Several factors limit diffusion of oxygen from the alveolus to blood at high altitude. Decreasing barometric pressure lowers alveolar PO_2 , which, in turn, decreases the pressure gradient for diffusion such that at altitudes above 2500 m even the estimated pulmonary capillary transit time at rest of 0.75 second may not be adequate for end-capillary equilibration of oxygen; diffusion limitation is exacerbated during exercise due to the shortened transit time of blood across the pulmonary capillary and the greater fall in mixed venous PO_2 . Because the low arterial PO_2 lies on the steep portion of the oxygen-hemoglobin dissociation curve, a small decrease in PO_2 will result in a proportionately greater drop in pulmonary capillary oxygen content than at sea level. West and Wagner²³ modeled these

factors for the summit of Mt. Everest ($P_B \sim 250$ mm Hg) and found that alveolar-capillary equilibration of oxygen is far from complete (Fig. 77-3).

With long-term residence at high altitude, the diffusing capacity of the lung increases, although the mechanism for this increase remains unclear. When compared to

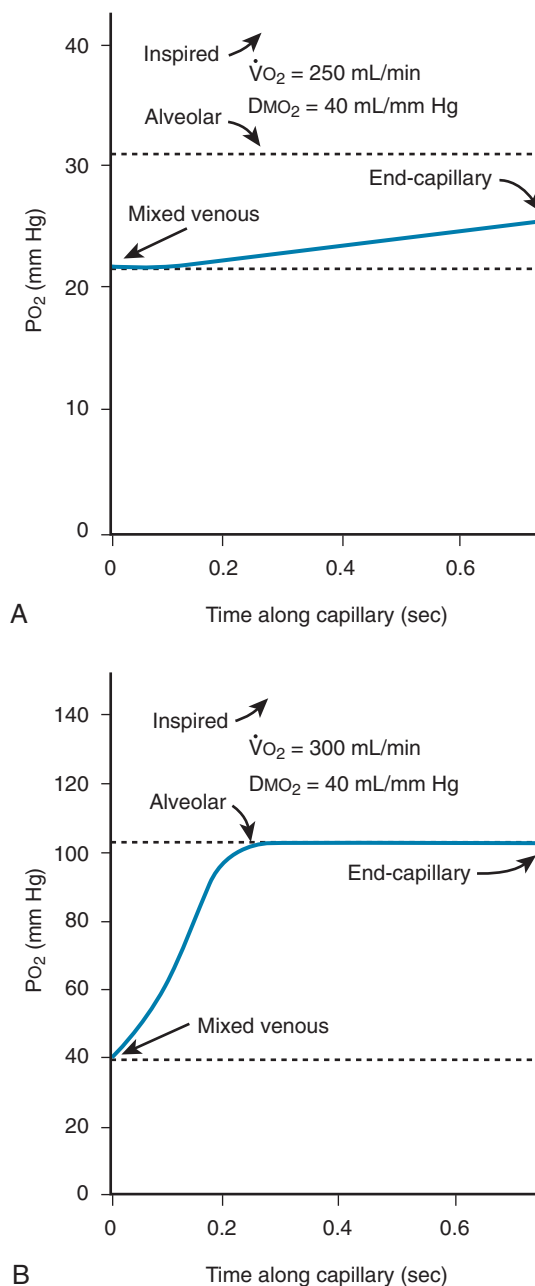

Figure 77-3 Comparison of the calculated time course of oxygen tension (PO_2) in the pulmonary capillary of a climber at rest on the summit of Mt. Everest (A) (barometric pressure = 250 mm Hg, inspired $PO_2 = 43$ mm Hg) to sea-level values (B) (barometric pressure = 760 mm Hg, inspired $PO_2 = 150$ mm Hg). At sea level, there is adequate time for equilibration of alveolar and end-capillary oxygen, whereas at extreme altitude, even at rest, when transit time for the red blood cell is presumably similar to that at sea level, full equilibration is not realized, resulting in end-capillary blood that is not fully saturated. \dot{V}_{O_2} , oxygen consumption; DMO_2 , diffusion capacity of the alveolar capillary membrane. (From West JB, Wagner PD: Predicted gas exchange on the summit of Mt. Everest. *Respir Physiol* 42:1–16, 1980.)

sojourners, high-altitude residents have a lower $(A - a)PO_2$ difference, increased diffusing capacity, and despite having lower ventilation, a higher arterial PO_2 at rest and during exercise.^{24,25}

CARDIOVASCULAR ADAPTATION

Cardiac Response

With acute hypoxia and decreased arterial oxygen content, cardiac output increases in an effort to maintain oxygen delivery so that, for any given work rate, cardiac output is higher than at sea level. After about 1 week, the relationship between cardiac output and work rate returns to that seen at sea level. The increase in cardiac output is explained largely by an increase in heart rate rather than a change in stroke volume. In fact, stroke volume actually declines upon initial exposure to high altitude and remains lower than sea-level values despite acclimatization. The lower stroke volume is not due to depressed myocardial function, according to studies that reveal evidence of preserved cardiac contractility in hypoxia²⁶; instead, it is likely due to diminished preload from a reduction in plasma volume. Systemic blood pressure increases in sojourners upon acute exposure to high altitude, likely due to increased sympathetic activity,²⁷ but decreases over time. In fact, in as few as 1 to 2 years after moving to high altitude, many people have lower systemic pressure, likely secondary to a vasodilatory effect of hypoxia on systemic arterial smooth muscle.

Hemodynamic Response

At high altitude, low alveolar PO_2 triggers vasoconstriction in the pulmonary vasculature, a response known as *hypoxic pulmonary vasoconstriction*, or HPV. Pulmonary artery pressure increases minimally until the alveolar PO_2 drops below 70 mm Hg, at which point a more marked rise ensues (Fig. 77-4). There is, however, substantial interindividual variability in this response.²⁸

Figure 77-4 Relationship of arterial oxygen tension (PaO_2) to minute ventilation (\dot{V}_E) and pulmonary arterial (PA) pressure. Although there is variability among individuals, both the ventilatory and the pulmonary vascular response do not increase until arterial PO_2 falls below 70 mm Hg. (From Reeves JT, Wagner WW Jr, McMurtry F, et al: Physiological effects of high altitude on the pulmonary circulation. In Robertshaw D, editor: *International review of physiology: environmental physiology III*. Baltimore, 1979, University Park Press, pp 289–310.)

Chronic hypoxic exposure results in even greater increases in pulmonary vascular resistance and pulmonary hypertension due to pulmonary vasoconstriction, hyperviscosity from polycythemia, and extensive vascular remodeling due to smooth muscle hypertrophy and collagen proliferation. The precise time course of these changes is not clear. In a 40-day simulated ascent of Mt. Everest (Operation Everest II), Groves and coworkers²⁹ exposed individuals to progressively lower inspired oxygen tensions and demonstrated an increase in pulmonary vascular resistance of more than threefold. Interestingly, after the 40 days, breathing 100% oxygen did not return the pulmonary vascular resistance to the sea-level baseline. This result suggests that the vasculature can remodel in just a few weeks. Depending on the severity of changes, particularly the degree of intimal fibrosis, reversal of pulmonary hypertension may require months or years at low altitude.³⁰

HEMATOLOGIC ADAPTATION

Erythropoietic Response

Hemoglobin concentration increases within 1 to 2 days of ascent and continues to rise for a number of weeks. The initial rise is due to hemoconcentration from a diuresis; further changes are due to increased red blood cell production, a result of hypoxia-mediated release of erythropoietin by the kidneys. Serum erythropoietin levels increase within 24 to 48 hours of ascent, and then decline over 3 weeks as acclimatization progresses.³¹ Both red blood cell volume and total blood volume increase. The erythropoietic response ceases on descent and hematocrit returns to sea-level values in approximately 3 weeks.

Although hematocrit generally increases with altitude, there is interindividual variability in the responses of both sojourners³² and highlanders.³³ Similar variability is seen among different highland populations, which may be genetically determined³⁴: Andean natives demonstrate greater erythropoiesis than either Himalayan or Ethiopian highlanders.³⁵ Whether greater erythropoiesis in Andean natives is secondary to genetic factors, environmental exposures, such as high levels of cobalt in and around mining regions,³⁶ or an up-regulation of the erythropoietic response to the renal sensing of hypoxia³⁷ is not clear.

While increasing hemoglobin concentration can augment arterial oxygen content, it may also impair oxygen delivery, in that, as the hematocrit approaches 60%, viscosity increases sufficiently to impair cardiac output and limit perfusion of the microvasculature.

Oxygen-Hemoglobin Affinity

Oxygen transport by blood is also influenced by the oxygen affinity of hemoglobin, as defined by the shape and position of the oxygen-hemoglobin dissociation curve. An important feature of the oxygen-hemoglobin relationship is the manner in which the dissociation curve steepens as arterial PO_2 falls below 60 mm Hg. As a result, with ascent to high altitude, arterial PO_2 falls into a range in which the oxygen content of hemoglobin drops precipitously with only small decreases in PO_2 .

To mitigate the potentially large impact on oxygen delivery, adaptations take place in the oxygen-hemoglobin

relationship. For example, with initial exposure to high altitude and the resultant respiratory alkalosis, the dissociation curve shifts to the left. This shift enhances oxygen loading in the lungs and increases arterial oxygen content but comes at the expense of potentially decreased oxygen off-loading in the tissues. Over time, the curve shifts back to the right in response to increased 2,3-diphosphoglycerate concentrations and renal compensation for the respiratory alkalosis and improves oxygen off-loading in the tissues.

Coagulation

Hemostasis has not been shown to change in a consistent manner, with conflicting results regarding the effect of high altitude on platelet counts, bleeding times, and markers of thrombin and fibrin formation.³⁸⁻⁴⁰ Increased fibrinogen levels and prolonged clot lysis times in patients with *high-altitude pulmonary edema* (HAPE)⁴¹ have been taken as evidence that thrombosis and platelet aggregation may contribute to this disease. Bartsch and associates,⁴² however, performed careful longitudinal studies while subjects were developing HAPE and concluded that platelet and coagulation changes had no causative role. Thromboembolic risk at altitude may be linked to the underlying coagulopathy,⁴³ but more work is necessary on this question.

TISSUE ADAPTATION

At the final stage of oxygen delivery, oxygen moves from plasma to the site of oxidative phosphorylation in the mitochondria. Driving pressures of 10 mm Hg may be needed for movement from capillary plasma to the cytoplasm while driving pressures of only 1 to 2 mm Hg are necessary for diffusion from cytoplasm to the mitochondria. At sufficiently high altitudes, the capillary P_{O_2} may fall to levels at which diffusion from plasma into the mitochondria is impaired. Structural and biochemical responses (e.g., diminished muscle fiber size that reduces diffusion distance from blood to mitochondria, increased myoglobin concentration, and increased levels or activity of enzymes involved in oxidative metabolism) help overcome this problem. Much of this structural and metabolic adaptation may be driven by gene transcription via hypoxia inducible factors 1 and 2, which are known to regulate many hundreds of genes involved in tolerance to hypoxia, such as erythropoietin, vascular endothelial growth factor, nitric oxide synthase, and numerous enzymes in intermediary metabolism.⁴⁴ Finally, recent evidence indicates that many cells express cytoglobins, heme proteins with oxygen-binding and transport characteristics similar to myoglobin, which may be up-regulated in hypoxia and play a role in adaptive responses.⁴⁵

CENTRAL NERVOUS SYSTEM ADAPTATION

Cerebral Blood Flow

On acute exposure, hypoxia triggers an increase in cerebral blood flow that is, in part, offset by hypocapnic-mediated cerebral vasoconstriction; the net result is a modest increase in cerebral blood flow,⁴⁶ which appears to be equally distributed between white and gray matter.⁴⁷ The acute cerebrovascular response may be biphasic in nature with an initial

decrease in cerebral blood flow due to acute hypocapnia followed by a subsequent increase triggered by arterial hypoxemia.⁴⁸ After 4 to 5 days, cerebral blood flow decreases but is still 13% greater than the sea-level value.⁴⁶ This increase in cerebral blood flow helps maintain oxygen delivery when arterial oxygen content is at its lowest until other adaptive mechanisms take effect and raise arterial oxygen content.

Cerebral Function

As one ascends, motor, sensory, and complex cognitive abilities are progressively impaired. New tasks are learned with difficulty at 3048 m, and simulated altitudes of 6100 m result in a decrement in sensory, perceptual, and motor performance. Short-term memory is impaired in climbers ascending without supplemental oxygen to 8500 m or higher.⁴⁹ Even acute, modest decreases in arterial SO_2 to 85% impair mental concentration and fine motor coordination; a further decrease to 75% results in poor judgment, irritability, and decreased muscle function.

It is difficult to predict which individuals will experience neurologic dysfunction at high altitude, but combined data from a field study on Mt. Everest and a chamber study simulating an ascent of Mt. Everest (Operation Everest II), demonstrated that individuals with a high HVR and higher arterial SO_2 had more pronounced neuropsychometric dysfunction.⁵⁰ One explanation for these findings is that those with a more brisk HVR might have greater hypocapnic cerebral vasoconstriction and, consequently, lower cerebral oxygen delivery.

A recent study in which brain *magnetic resonance imaging* (MRI) was performed on climbers who had ascended to summits between 5895 and 8848 m demonstrated evidence of subcortical lesions suggestive of small infarctions.⁵¹ The study did not correlate these findings with symptoms or signs of neurologic dysfunction and did not include follow-up studies to determine whether these lesions resolved, but the results raise the question as to whether high-altitude exposure causes permanent cerebral injury and whether the observed dysfunction at high altitude persists over time. Existing evidence suggests that the transient deterioration in learning, memory, and expression of verbal material return to baseline within 1 year but that fine motor coordination problems may persist for longer periods of time.^{50,52}

Cellular Adaptive Mechanisms

As with cytoglobin up-regulation in peripheral tissues, intracerebral expression of neuroglobin, another protein related to hemoglobin and myoglobin, is increased during hypoxic stress and may play a role in limiting neuronal dysfunction or injury.⁵³

FLUID HOMEOSTASIS AND RENAL FUNCTION

Upon ascent to high altitude, there is diuresis and natriuresis and, as with the HVR, these peripheral chemoreceptor-mediated responses vary almost 10-fold between individuals over the first 24 to 48 hours at altitude.⁵⁴ Following acclimatization, further gains in elevation may lead to additional diuresis and natriuresis.⁵⁵ The mechanism underlying this observed diuresis and natriuresis is not clear, but it does not

appear to result from changes in renin, angiotensin, aldosterone, or atrial natriuretic peptide levels. In acute hypoxia, urinary protein excretion increases twofold to threefold, and with high-altitude illness, urinary protein excretion increases further.

CHANGES IN COMMON SEA-LEVEL ACTIVITIES AT HIGH-ALTITUDE

SLEEP

Difficulty sleeping is a common problem at high altitude. In studies examining pharmacologic prophylaxis for *acute mountain sickness* (AMS), for example, more than 70% of people receiving placebo reported poor-quality sleep.⁵⁶ In addition to subjective impressions of sleep impairment, there is objective evidence of poor sleep, with increased arousals, changes in sleep architecture, and an increased incidence of periodic breathing (Video 77-1).⁵⁷ In addition, it is during sleep that both sojourners and natives experience the most severe hypoxemia, because steep, transient drops in oxygen saturation often accompany apneic periods.

The mechanisms underlying periodic breathing at high altitude have been reviewed elsewhere.⁵⁸ The consensus is that sleep eliminates most cortical influences on respiration, leaving hypoxemia via carotid chemoreceptors as the prominent drive. The effect of hypoxia-induced changes in PCO_2 on hypoxic drive may set up oscillations of ventilation in a poorly damped system. At moderate altitudes (<3000 m), this periodic breathing diminishes over several days as ventilatory acclimatization proceeds, but at higher altitudes periodic breathing persists for long periods of time.⁵⁹

Periodic breathing during sleep at high altitude can be eliminated by breathing supplemental oxygen (Fig. 77-5) and can be reduced through the use of respiratory stimulants such as acetazolamide.⁶⁰ A review of trials of acetazolamide in AMS prophylaxis demonstrates that sleep was also improved in the acetazolamide groups compared to the placebo groups.^{56,61} More recently, the benzodiazepine class drug temazepam has also been shown to reduce the incidence of periodic breathing and improve measures of sleep quality without a negative effect on next-day reaction

Figure 77-5 Periodic breathing in lowlander at 5400 m during sleep while breathing ambient air (left half of tracings) and oxygen (right half of tracings). Upper panel is tidal volume (VT, inspiration downward), and lower panel is arterial oxygen saturation (SAO_2 , %). (From Lahiri S, Maret K, Sherpa MG: Dependence of high-altitude sleep apnea on ventilatory sensitivity to hypoxia. *Respir Physiol* 52:281–301, 1983.)

times or maintenance of wakefulness.⁵⁹ Gamma aminobutyric acid receptor agents, including zolpidem and zaleplon, can also improve sleep quality and sleep architecture, but there is no evidence that either agent decreases periodic breathing.⁶²

EXERCISE

Exercise at high altitude is different in many important respects from exercise at sea level.

Maximal Work

With acute and prolonged hypoxic exposures, maximal oxygen consumption ($\dot{V}O_{2max}$) and work capacity are decreased relative to sea-level values.^{63,64} $\dot{V}O_{2max}$ decreases about 10% per 1000 m of altitude gain so that, at approximately 0.5 atm, $\dot{V}O_{2max}$ is about half of its sea-level value and, at 0.33 atm (as at the summit of Mt. Everest), $\dot{V}O_{2max}$ is about 23% of that at sea level. Because maximum oxygen uptake is decreased at altitude, maximum minute ventilation and heart rate at peak exercise are also reduced compared to their sea-level values (Fig. 77-6).⁶³

Ventilation

Because of the decrease in air density and the lower amount of oxygen, greater ventilation is required to achieve the same oxygen uptake at high altitude. As a result, the ventilatory response to exercise is augmented at altitude compared to sea level.⁶³ For example, with a sojourn to 6300 m, the ventilation for a given metabolic rate (the ventilatory equivalent, $\dot{V}E/\dot{V}O_2$) is almost four times as great as at sea level. The increase is a function of both the altitude attained

Figure 77-6 Maximal ventilation ($\dot{V}E_{max}$), respiratory frequency, and heart rate versus inspired PO_2 . At a PO_2 of 64 mm Hg (equivalent to an elevation of 6300 m), $\dot{V}E_{max}$ is increased to a maximum of over 200 L/min because of the stimulation to ventilation from hypoxia as well as a decreased density of the inspired air, whereas at a PO_2 of 43 mm Hg (equivalent to an elevation more than 8000 m such as on Mt. Everest), $\dot{V}E_{max}$ is decreased, probably as a result of a diminished metabolic demand from low work rates. Respiratory frequency continues to increase. Maximum heart rate decreases with increasing altitude. (From West JB, Boyer SJ, Graber DJ, et al: Maximal exercise at extreme altitudes on Mount Everest. *J Appl Physiol* 55:688–702, 1983.)

and the strength of the individual's HVR.⁶⁵ The increase in ventilation comes at a price, however. At extreme altitude, the oxygen cost of breathing during exercise may be as high as 40% of the overall metabolic rate and may result in allocation of cardiac output to respiratory muscles that could otherwise be dedicated to muscles of locomotion. Extreme dyspnea with exercise may affect the intensity and duration of exercise; with rest, dyspnea typically resolves rapidly.

Gas Exchange

Unlike at sea level, where arterial oxygen saturation remains constant with increasing workloads in most normal individuals, it decreases with increasing workloads following either short⁶⁶ (Fig. 77-7) or long duration high-altitude exposures.⁶³ Alveolar hypoxia decreases the driving gradient for diffusion while pulmonary capillary transit time is shortened as a result of the increase in cardiac output, thereby creating a true diffusion limitation (see Fig. 77-3). \dot{V}_A/\dot{Q} mismatching may also contribute to the observed gas exchange abnormalities⁶⁶; nonuniform hypoxic pulmonary vascular response may lead to interstitial pulmonary fluid accumulation, which, in turn, creates \dot{V}_A/\dot{Q} heterogeneity and impairs gas exchange.

Cardiovascular Response

For any given *submaximal* work rate, cardiac output and heart rate are higher during exercise at altitude compared to sea level. With acclimatization, cardiac output at submaximal workloads returns to sea-level values while the heart rate remains elevated. However, *maximal* exercise capacity and peak heart rate and cardiac output at altitude are reduced relative to sea-level values. With acclimatization, maximal exercise capacity is not restored to sea-level

values over time and maximum cardiac output, heart rate, and stroke volume all remain decreased.²⁶

Pulmonary artery pressures reach high levels during exercise at high altitudes.²⁹ Whether these high pressures limit exercise capacity at altitude is not clear. On the one hand, because cardiac output is maintained at levels appropriate for the work rates attained, the increase in pulmonary vascular resistance in healthy sojourners to high altitude would not appear to limit exercise. However, in a field study of acclimatized individuals,⁶⁷ administration of the phosphodiesterase inhibitor sildenafil prior to a maximum exercise test at 5245 m lowered pulmonary artery systolic pressure and improved maximum exercise capacity compared to placebo, but other studies have not confirmed this.⁶⁸ Alternatively sildenafil improves arterial oxygenation, which may explain the greater exercise capacity.⁶⁹ Thus, it remains unresolved whether the rise in pulmonary artery pressures contributes to limiting exercise capacity at high altitude.

Exercise Performance at High Altitude

The effect of altitude on exercise performance varies based on the type of activity and the duration of stay at high altitude. Performance for running events of less than 2 minutes' duration at less than 3000 m altitude is not impaired and may even be slightly improved because of decreased air density and resistance. Performances in events of longer duration are predictably diminished and can be restored only part way to sea-level capacity with prolonged stays at high altitude. Finally, as noted earlier, maximum oxygen consumption, peak heart rate, and peak minute ventilation are reduced at high altitude. Regardless of the duration of stay or the intensity of training, these values do not return to sea-level values.

Training at High Altitude

There is considerable interest in whether living and training at high altitude improves performance at lower elevations. In the past, many elite endurance athletes relocated to and trained at moderate altitudes of 2000 to 2500 m, but the beneficial effects on performance after return to sea level were generally not realized, because athletes could not attain the same maximum speeds and power output during training at altitude that they needed to reach during their sea-level races. More recently, interest has been raised in using intermittent hypoxic exposure as an alternative means to apply the benefits of high-altitude acclimatization to sea-level performance. For example, Beidleman and colleagues⁷⁰ found that intermittent exposure to 4300-m altitude for 3 weeks improved speed and endurance in trained cyclists. In their landmark study, Levine and coworkers⁷¹ studied four well-matched groups of athletes: (1) those who lived low and trained low (1350 m), (2) those who lived low and trained high (3000 m), (3) those who lived high and trained high, and (4) those who lived high and trained low. The group that lived high and trained low seemed to have gained the benefit of hypoxic conditioning while not losing the intensity of training sessions. This advantage was presumably due to the modestly elevated hemoglobin from the altitude exposure, although there was individual variability in the erythropoietic response that correlated with improvement in performance.⁷²

Figure 77-7 Arterial oxygen saturation with exercise at altitude. Arterial oxygen saturation (%) does not decrease with exercise at sea level but drops progressively with higher workloads at greater altitudes. There is a diffusion limitation of oxygen transfer across the alveolar-hemoglobin interface. (From West JB, Boyer SJ, Graber DJ, et al: Maximal exercise at extreme altitudes on Mount Everest. *J Appl Physiol* 55:688–702, 1983.)

Because of the limited access to high altitude for many athletes, recent interest has focused on “bringing the mountain to the athlete”⁷³ by having the athlete spend time each day in oxygen-depleted tents that can be set up in their home or training center. The key question that has emerged from this practice and the studies noted, however, is this: What “dose” of hypoxic exposure and what level of athletic capacity is necessary to see a benefit in sea-level performance? A review of studies on the topic concluded that athletes needed to reside at 2000–2500 m for at least 4 weeks for at least 22 hours/day in order to derive physiologic benefit from the live high–train low model.⁷³ However, a recent placebo-controlled trial in which elite athletes were blinded to whether they were in the “live high” group found no benefit to this strategy.⁷⁴

MALADAPTATION

The physiologic adaptations described earlier give most individuals the ability to tolerate high-altitude exposure. Regardless of the ultimate altitude achieved, however, individuals who ascend too rapidly to altitudes above 2500 m may display maladaptive responses and develop one of three forms of acute altitude illness: AMS, HAPE, and *high-altitude cerebral edema* (HACE). Because the risk of such illnesses decreases as individuals spend more time at altitude, long-term residents are not susceptible to these problems. However, several forms of chronic altitude illness, chronic mountain sickness and right heart failure, can affect these populations and represent important public health concerns.

PROBLEMS OF LOWLANDERS ON ASCENT TO HIGH ALTITUDE

Susceptibility to Altitude Illness

The incidence and severity of acute altitude illness depend on several factors, including the rate of ascent, the length of stay, and individual susceptibility. A trip to and from high altitude on the same day poses much less risk than an overnight stay because hypoxia is accentuated during sleep and because more prolonged exposure is associated with the overnight stay. Susceptibility to altitude illness varies considerably among individuals but, for a single individual, the symptoms are often reproducible given the same rate of ascent and other circumstances. Whereas men and women are equally susceptible to AMS,^{75,76} younger adults⁷⁵ and the obese⁷⁶ may be slightly more vulnerable. Recent trips to high altitude⁷⁷ and residence at moderate altitude (>1900 m)⁷⁸ have a protective effect. Of note, being in good physical condition does not exert any protective effect.⁷⁹ There are insufficient data regarding whether preexisting chronic illnesses increase susceptibility.

At present, there are no adequate means to predict who will get sick upon ascent to high altitude. Variables such as the HVR⁸⁰ and arterial oxygen saturation during hypoxic exposure⁸¹ have been proposed as useful predictors for developing AMS, but have not been validated in further studies, while specific genetic markers that reliably predict susceptibility have also yet to be identified.⁸² Richalet and

colleagues⁸³ have proposed a model to identify patients with risk factors for severe high-altitude illness, but this prediction tool requires the use of cardiopulmonary exercise testing under hypoxic conditions to identify susceptible individuals and, as a result, can be difficult to implement on a wide basis.

HAPE-susceptible individuals have been shown to have intense HPV and exaggerated pulmonary vascular responses to resting hypoxia and normoxic exercise,^{28,64} but this relationship has not been validated in prospective studies. In the end, the only useful predictive tool remains the patient's prior experience at high altitude, particularly when the ascent rate and altitude of the prior and planned sojourns are similar.

Acute Mountain Sickness

AMS is the most common form of acute altitude illness, affecting 22% to 50% of travelers to altitudes between 1850 and 4240 m.^{75,76} Because of increasing awareness of the risks of altitude illness among the general population, incidence rates have likely fallen in commonly traveled regions, but very high incidence rates (up to 70%) continue to be reported with rapid ascents to high elevations in certain regions such as Mt. Kilimanjaro.⁸⁵

Clinical Presentation. AMS is marked by the presence of headache plus one or more other symptoms including lassitude, insomnia, anorexia, nausea, dizziness, and, in severe cases, vomiting, although recent debate has developed as to whether headache is required for diagnostic purposes.^{86,87} Symptoms do not start immediately upon ascent and, instead, come on over many hours following arrival at altitudes above 2400 m (8000 feet), with the elevation at which symptoms begin varying significantly between individuals. Although many people complain of a sense of oppression in the chest, there is rarely any respiratory distress when the patient is at rest.

There are no characteristic physical examination findings in AMS, although crackles on auscultation and peripheral edema have been documented in some reports.^{88,89} No consistent changes are seen in body temperature, with some studies reporting a mild increase in temperature⁹⁰ and others reporting a decrease of 1.7°C with no change in metabolic rate.⁹¹ Oxygen saturation values may be lower in individuals with AMS compared to those who remain healthy,^{92,93} but AMS can still be seen in those with what would be considered normal oxygenation at a particular altitude.

The symptoms and signs of AMS are nonspecific and other causes must be considered on the differential diagnosis, including dehydration, hypothermia, hyponatremia, exhaustion, alcohol hangover, carbon monoxide poisoning, and respiratory or cerebral infections. The diagnosis is based solely on the clinical history and there are no confirmatory laboratory tests. For a diagnosis of AMS and not the more severe HACE, the patient must have normal neurologic and mental status examinations.

Natural Course of Untreated AMS. In a study of Indian soldiers⁸⁸ airlifted to 3300 to 5500 m, incapacitating illness lasted 2 to 5 days but full recovery often took longer; 38% recovered fully within 3 days, 40% were still ill after 1 week,

and 13% had symptoms after 1 month. In tourists sleeping at a lower altitude (2700 m), symptoms lasted an average of 15 hours (range: 6 to 94 hours).⁹⁴ Most individuals tolerate or treat their own symptoms as the illness resolves over 1 to 3 days, but some persons with AMS seek medical help or are forced to descend. HACE or HAPE develops in a small percentage of those with AMS, especially when ascent is continued despite illness.

Pathophysiology. Current concepts of pathophysiology emphasize the cerebral etiology of AMS. In severe illness, elevated intracranial pressure and cerebral edema have been noted on neurologic imaging⁹⁵ and brain biopsy.⁸⁸ Brain MRI studies⁹⁵ have demonstrated swelling in the white matter and none in the gray matter in patients with HACE, a finding that suggests the edema is vasogenic in origin and initially confined to the white matter. Brain MRI also shows slightly increased brain volume and decreased intracerebral CSF volume in patients with AMS than in those without symptoms.⁹⁶ Subsequent studies revealed conflicting data, with some reporting no evidence of changes consistent with cerebral edema⁹⁷ and others⁹⁸ showing evidence of mild increases in brain volumes and evidence of cytotoxic edema in subjects with mild to moderate AMS. It has been suggested that development of AMS may depend to some extent on the ability to shift CSF out of the cranium, and those individuals with smaller ventricles and CSF spaces may be at a disadvantage. This argument, referred to as the “tight-fit” hypothesis, might explain the increased susceptibility of younger persons, because age-related increases in the volume of sulci in older persons may provide more room to accommodate mild brain swelling.⁹⁹

Although evidence suggests that cerebral edema plays a role in severe AMS, it remains unclear whether this causes milder forms of the disease. There is only one study of intracranial pressure in subjects with early AMS, and it failed to demonstrate an increase in CSF pressure.⁹⁹ Because headaches arise early in AMS at a time when edema and significant increases in intracranial pressure are unlikely, alternative explanations should be considered. The classic explanation that the headache and other symptoms of AMS are due to cerebral vasodilation alone seems unlikely, because the severity of AMS symptoms has not been shown to correlate with middle cerebral artery blood flow velocity.¹⁰⁰ Limited evidence that sumatriptan, a 5-HT₁ receptor agonist, can prevent AMS¹⁰¹ or treat high-altitude headaches¹⁰² suggests that abnormal cerebrovascular reactivity or neuropeptide responses play a role in AMS pathophysiology. Another explanation is that hypoxia-induced changes in the blood-brain barrier alter permeability to plasma compounds with potential neurotoxicity or irritation. In studies in animals and cell cultures, hypoxia has been shown to mediate increased permeability of the blood-brain barrier to large molecules, but this has not been observed in humans.⁹⁸ The mechanism underlying these blood-brain barrier changes is unclear, but factors such as oxygen free radical species and vascular endothelial growth factors have been proposed as possible contributors.^{103,104}

The findings in severe AMS of possible cerebral edema, peripheral edema, and proteinuria also suggest that there may be a defect in salt and water homeostasis and an increase in capillary permeability. AMS-susceptible indi-

viduals have elevated aldosterone and antidiuretic hormone levels when compared with controls, while persons acclimatizing well exhibit diuresis, net water loss, and low antidiuretic hormone values.¹⁰⁵ A relatively recent study confirmed the findings regarding antidiuretic hormone but found no difference in aldosterone levels between healthy controls and those with AMS.¹⁰⁶ These alterations in hormone levels cannot be attributed to a generalized increase in systemic capillary permeability or endothelial cell dysfunction, in that subjects with and without AMS demonstrate no differences in the global transvascular escape of labeled protein.¹⁰⁷

Hypoventilation may also contribute to the development of AMS. Acetazolamide and theophylline, two medications with respiratory stimulant properties, prevent the disorder^{61,108} and a brisk increase in ventilation on ascent to altitude has been associated with a lower incidence of AMS.⁸⁰ At the same time, however, prospective studies have not demonstrated a correlation between a lower HVR measured before ascent and the development of AMS at high altitude.¹⁰⁹ Bartsch and coworkers¹⁰⁹ demonstrated that relative hypoventilation developed in subjects with early AMS compared to well-adapting subjects, suggesting that the blunted HVR was a response to AMS rather than a cause.

Prevention. Appropriate pharmacologic and nonpharmacologic measures to prevent or ameliorate AMS have been described in recently published guidelines.¹¹⁰ Because overly rapid ascent to high elevation is the leading risk factor for altitude illness, gradual ascent, with rest days for acclimatization, is considered the single best way to prevent all forms of altitude illness. It is recommended that above 3000 m, individuals should increase their sleeping elevation by no more than 300 to 500 m per night and should take an acclimatization day and sleep at the same elevation a second night every 3 to 4 days or after any large gain in elevation. Only a single study has attempted to study the benefits of slow ascent in a randomized, controlled manner,¹¹¹ and strict adherence to published recommendations may be difficult due to a variety of logistical factors. Travelers should avoid overexertion. They should refrain from heavy alcohol consumption or narcotic medication use, particularly before bedtime, in order to avoid hypoventilation, which can exacerbate the hypoxemia of high altitude. These strategies have never been subjected to rigorous study but represent common sense measures in light of the known physiologic changes at altitude.

Pharmacologic means can also be used to prevent AMS. The most commonly used medication for this purpose is acetazolamide.^{61,75} Its principal action is renal carbonic anhydrase inhibition, which causes a bicarbonate diuresis and a metabolic acidosis, which, in turn, stimulates ventilation, increases alveolar PO₂, and enhances oxygen off-loading in the tissues. In effect, the drug speeds natural acclimatization by accelerating the pace of ventilatory adaptation by several days. Actions of acetazolamide on carbonic anhydrase elsewhere in the body, such as the peripheral and central chemoreceptors, may also contribute to its preventive role.¹¹²

Debate persists about the proper dose of acetazolamide,¹¹³ but most published resources continue to recommend a

Table 77-2 Dosing and Use of Altitude Illness Medications in Normal Persons and in Patients with Underlying Disease

Medication	Dose in Normal Individuals	Liver Disease	Chronic Kidney Disease	Other Major Dosing Issues
Acetazolamide	AMS prevention: 125 or 250 mg bid AMS treatment: 250 mg bid	Use is contraindicated	Avoid use in patients with GFR < 10 mL/min, metabolic acidosis, hypokalemia, hypercalcemia, and hyperphosphatemia or recurrent nephrolithiasis	Avoid in patients on long-term high-dose aspirin or with ventilatory limitation (FEV ₁ < 25% predicted) Caution in patients with documented sulfa allergy Avoid concurrent use of topiramate
Dexamethasone	AMS prevention: 4 mg bid or 2 mg qid HACE treatment 8 mg once followed by 4 mg every 6 hours	No contraindication; no dose adjustments necessary	No contraindication; no dose adjustments necessary	Expect elevated blood glucose values when used in diabetic patients Avoid in patients at risk for peptic ulcer disease or upper gastrointestinal bleeding Caution in patients at risk for amebiasis or strongyloidiasis
Nifedipine	HAPE prevention: 20 to 30 mg of sustained release version every 12 hours HAPE treatment: 20 to 30 mg of sustained release version every 12 hours	Reduced dose required (10 mg bid)	No contraindication; no dose adjustments necessary	Caution in patients taking medications metabolized by CYP450 3A4 and 1A2 pathways Caution during concurrent use with other antihypertensive medications
Tadalafil	HAPE prevention: 10 mg bid HAPE treatment: Unknown	Child's class A and B: Maximum 10 mg daily Child's class C: Do not use tadalafil	Dose adjustments necessary if GFR < 50 mL/min. If GFR 30–50 mL/min, use 5-mg dose, maximum 10 mg in 48 hr. If GFR < 30 mL/min, no more than 5 mg	Increased risk for gastroesophageal reflux Caution in patients taking medications metabolized by CYP450 3A4 pathway Avoid concurrent use of nitrates or α -blockers
Sildenafil	HAPE prevention: 50 mg every 8 hours HAPE treatment: Unknown	Dose reductions recommended. Starting dose 25 mg tid Avoid use in patients at risk for variceal bleeding	Dose adjustments necessary if GFR < 30 mL/min	Increased risk for gastroesophageal reflux Caution in patients taking medications metabolized by CYP450 3A4 pathway Avoid concurrent use of nitrates or α -blockers
Salmeterol	HAPE prevention: 125 μ g bid HAPE treatment: No established role in HAPE treatment	Insufficient data	No contraindication; no dose adjustments necessary	Avoid concurrent use of β -blockers, monoamine oxidase inhibitors or tricyclic antidepressants Possible adverse effects in coronary artery disease patients prone to arrhythmia

AMS, acute mountain sickness; FEV₁, forced expiratory volume in 1 second; GFR, glomerular filtration rate; HACE, high-altitude cerebral edema;
HAPE, high-altitude pulmonary edema

dose of 125 to 250 mg twice a day^{96,110} (Table 77-2). Acetazolamide is well tolerated with the most common side effect being paresthesias involving the hands, feet, and lips. There may be nausea and drowsiness, and carbonated beverages may taste flat, probably secondary to the inhibition of hydration of carbon dioxide on the palate. Acetazolamide has a sulfonamide moiety and shares the cautions common to all sulfa drugs. The likelihood of a cross reaction is low (approximately 7% to 10%),¹¹⁴ but case reports describe fatal anaphylactic reactions in people with documented sulfa allergy who received acetazolamide.¹¹⁵

For patients who do not tolerate or cannot take acetazolamide, dexamethasone is an effective alternative for AMS prophylaxis.¹¹⁶ Studies comparing dexamethasone and acetazolamide have revealed approximately equal effectiveness of the two drugs in preventing AMS.¹¹⁷ Dexametha-

sone does not speed the acclimatization process and may be associated with reappearance of symptoms if it is abruptly discontinued. Suggested doses are listed in Table 77-2.

As noted earlier, theophylline can prevent AMS but given the narrow therapeutic window of the medication, it should not be used for this purpose. Conflicting results have been reported regarding the effects of ginkgo biloba on AMS prevention,^{118,119} likely as a result of variable production standards between manufacturers,¹²⁰ and as a result, the supplement should not be used for AMS prophylaxis. Recent attention has also focused on a potential role for ibuprofen in AMS prevention,¹²¹ but it has yet to be proven superior to acetazolamide for this purpose and is not part of standard recommendations at this time.¹¹⁰

In most cases, pharmacologic prophylaxis is not necessary, in that a slow ascent is usually sufficient to prevent

AMS. Pharmacologic prophylaxis may be reserved for those with a known increased risk for altitude illness, as for people with known susceptibility to AMS who are returning to altitudes at which they have been sick in the past, people flying into high-altitude destinations (e.g., La Paz, Bolivia), or people whose work mandates a rapid ascent (e.g., rescue teams).¹¹⁰

Treatment. In general, descent leads to resolution of all forms of altitude illness. Patients with mild illness may not require descent, however, and often recover by remaining at the same elevation and resting for a period of time. In more severe illness, descent is indicated and should continue until symptoms resolve. How much descent is required varies depending on the severity of the case; less severe illness may resolve with descent of only 300 m while more severe illness may require further drops in altitude. At times, because of field conditions, descent may not be feasible and alternative treatments are necessary. Severely ill patients can be placed on supplemental oxygen if gas tanks or an oxygen concentrator are available or “low altitude” can be brought to the patient through the use of lightweight portable hyperbaric chambers (Fig. 77-8). These chambers can be pressurized to 2 psi and mimic a descent of approximately 1500 m. By means of a foot pump, sufficient gas flow is maintained to keep the carbon dioxide concentration low and the oxygen concentration close to 21%.¹²² Studies demonstrate that the chamber is as effective as administering supplemental oxygen with an FIO_2 of 0.26 to 0.3, although the therapy is difficult to implement with claustrophobic individuals or those who are vomiting. As with oxygen therapy, relief of symptoms is generally immediate, but long treatment times are needed in severe illness and to ensure sustained improvement upon removal from the chamber.¹²²

Figure 77-8 A portable hyperbaric chamber used to treat severe altitude illness when supplemental oxygen is not available or descent is not feasible. The sick individual is placed in the bag, which is then closed using an air-sealed zipper. A foot pump is used to inflate the bag and increase the barometric pressure within it. Visual contact is maintained through plastic windows in the wall of the bag while verbal communication can be maintained across the wall of the bag. Once inflated to the target pressure, the bag must be pumped on a continual basis to maintain the target pressure and ensure adequate ventilation. Depending on the pressure to which the bag is raised, it is possible to simulate a descent of 2000 to 5000 feet (600 to 1500 m) for the individual inside the bag. (Copyright Andrew Luks, MD.)

Acetazolamide can ameliorate symptoms of AMS and improve arterial oxygenation,¹²³ while aspirin,⁸⁸ ibuprofen,¹²⁴ and acetaminophen¹²⁴ have been shown to treat the headache associated with AMS. Prochlorperazine is useful for treating nausea and vomiting and, unlike some other antiemetics, may actually increase rather than depress ventilation.¹²⁵ Even if it is not being used for AMS prophylaxis, dexamethasone should be part of the high-altitude traveler's medical kit, especially in remote areas of the mountains, because rapid treatment of evolving symptoms with dexamethasone may keep the patient ambulatory, allowing a rapid descent without need for an expensive evacuation.

High-Altitude Cerebral Edema

HACE is a potentially fatal form of acute altitude illness defined by the onset of mental status changes and/or ataxia in a person with AMS, or by the presence of both neurologic signs in a person without AMS who has recently ascended to altitude. It usually develops at higher altitudes than AMS.

In addition to ataxia and altered level of consciousness, many people develop an incapacitating headache, persistent nausea and vomiting, and debilitating lassitude. Affected individuals may also develop one of many neurologic symptoms and signs including papilledema, visual changes, cranial nerve palsies, bladder dysfunction, abnormal reflexes, paresthesias, pareses, aphasia, clonus, hallucinations, seizures, and behavioral changes.⁷⁵ If the disease is not recognized and treated promptly, coma and death may ensue.

While incidence rates of 0.53% to 1.25% have been reported,^{88,126} the true incidence is difficult to assess because the boundary of progression from AMS may be hard to define and the symptoms and signs may be similar to those of cerebral hypoxia secondary to severe hypoxemia from pulmonary edema. The differential diagnosis includes all other causes of encephalopathy, such as carbon monoxide poisoning, hypertensive crisis, severe cerebral hypoxia secondary to HAPE, meningitis, hypoglycemia, moderate to severe hypothermia, and migrainous encephalopathy. Because HACE is generally a problem of global neurologic dysfunction marked by gradual onset over a period of hours, a sudden onset and/or presence of focal neurologic deficits, high temperature, or neck stiffness should prompt consideration of alternative diagnoses. Diagnosis in the field is based on the clinical history and clinical examination. Heel-to-toe walking along a straight line is an effective test for the presence of ataxia (Video 77-2). When advanced diagnostic modalities are available, MRI reveals a pattern of reversible increased T2-weighted signal in the corpus callosum and, in particular, the splenium, which may help differentiate HACE from other conditions.⁹⁵

In persons who die of HACE, pathology reports reveal gross cerebral edema.¹²⁷ Findings include swelling and flattening of the cerebral gyri, compression of the sulci, herniation of cerebellar tonsils and uncus, small petechial hemorrhages, and venous and sinus thromboses. Brain MRI performed in patients with nonfatal HACE also reveals evidence of hemosiderin deposition, a finding consistent with the presence of microhemorrhages.¹²⁸

The definitive treatment for HACE is descent, although recovery is not as rapid as in AMS and HAPE, and descents

Figure 77-9 High-altitude pulmonary edema. **A**, Typical chest radiographic appearance of high-altitude pulmonary edema in a 15-year-old boy. Note that the edema is unilateral and predominantly right sided. **B**, Severe high-altitude pulmonary edema in a 27-year-old man. Note the normal heart size and the presence of bilateral opacities in this case. (Courtesy of Peter Hackett.)

of more than 1000 m may be necessary. If descent is not possible, oxygen or hyperbaric therapy may be lifesaving temporizing measures. In the only study of therapy, severe neurologic symptoms and signs responded to furosemide and betamethasone, although the drugs were not studied separately or in a prospective manner.⁸⁸ Dexamethasone is now routinely used in HACE management (see Table 77-2). Mannitol and glycerol have been suggested for treatment but are difficult to use safely in the field due to lack of adequate monitoring of serum osmolality and volume status and should only be used in a hospital or clinic setting.

High-Altitude Pulmonary Edema

HAPE is the most common cause of death from high-altitude illness. It was previously misdiagnosed as pneumonia, bronchitis, or congestive heart failure until reports by Hultgren and colleagues⁸⁴ and Houston¹²⁹ revealed it to be a distinct form of noncardiogenic pulmonary edema.

Clinical Presentation. HAPE typically manifests within 2 to 4 days of ascent to altitudes above 2400 m (8000 feet), most commonly beginning on the second night. In the early stages of the disease, decreased exercise performance develops and individuals require increasing amounts of time to recover from exertion. Individuals also complain of fatigue, weakness, and a persistent dry cough; symptoms of AMS may also be present. As the disease worsens, individuals become short of breath with minimal exertion. Dyspnea at rest, audible chest congestion, and production of pink frothy sputum are late findings in severe disease. Even in the absence of concurrent HACE, severe hypoxemia may produce mental changes, ataxia, and altered levels of consciousness.

On physical examination, the patient often appears better than one would expect based on blood gases and radiographic findings. There may be a low-grade fever to 38.5°C, as well as tachycardia and tachypnea. Crackles are initially heard in the right mid-lung fields and then more diffusely as the disease worsens. Generalized pallor and nail bed cyanosis may be noted. Radiographs and computed tomogra-

phy scans show patchy, alveolar opacities, which may be limited to one area (the right lung field predominating initially) or generalized, depending on illness severity (Fig. 77-9). Arterial blood gases reveal severe hypoxemia. In a study at 4559 m, for example, individuals with HAPE had a mean arterial PO_2 of 23 ± 3 mm Hg and an average saturation of $48 \pm 8\%$ versus 40 ± 5 mm Hg and $78 \pm 7\%$ for healthy controls.¹³⁰ Pulmonary artery pressure is high, but pulmonary wedge pressure is normal and heart size is not increased.⁸⁴

Pathologic Findings. A total of 22 autopsies have been reported in persons dying of HAPE.^{88,131} A red cell-rich proteinaceous exudate with hyaline membranes is characteristic. All had some areas of pneumonitis with neutrophil accumulation but no evidence of bacterial accumulation. Pulmonary veins were not dilated. Most reports mention capillary and arteriolar thrombi, fibrin deposits, hemorrhage, and infarcts.

Bronchoalveolar lavage samples obtained within the first 24 hours of ascent to 4559 m have demonstrated an increase in red blood cells and protein but an absence of inflammatory mediators and neutrophils,¹³² whereas samples obtained later in the disease process show even more protein, neutrophilia, and evidence of inflammation marked by such inflammatory mediators as leukotriene B_4 and thromboxane B_2 ,¹³³ as well as interleukin-1, -6, and -8, and tumor necrosis factor- α .¹³⁴

Possible Mechanisms. HAPE is a form of noncardiogenic pulmonary edema. Left ventricular function and pulmonary capillary wedge pressure remain normal. Although the mechanisms underlying HAPE remain incompletely understood, it appears that elevated pulmonary artery pressures play a central role in the process, in that multiple investigations have shown that affected individuals have markedly elevated pulmonary artery pressures compared to healthy controls.^{84,135}

HAPE-susceptible individuals have exaggerated HPV, which likely accounts for their elevated pulmonary artery

pressures; multiple studies demonstrate that HAPE-susceptible individuals have abnormally high pulmonary artery pressure responses during hypoxic breathing, during normoxic and hypoxic exercise, and on ascent to high altitude before the onset of edema.^{28,136} A lower HVR^{137,138} and slightly lower lung volumes¹³⁸ may also contribute to increased pulmonary artery pressure by increasing alveolar hypoxia and reducing the number of recruitable vessels. Finally, evidence suggests that increased sympathetic tone¹³⁹ and alterations in vasoactive mediators (*endothelin* [ET-1], *nitric oxide* [NO]) produced by pulmonary endothelial cells¹⁴⁰ may also lead to stronger HPV.

The levels of ET-1, a potent endothelial-derived pulmonary vasoconstrictor, are elevated in HAPE-susceptible individuals¹⁴⁰ and correlate with a rise in pulmonary artery pressures, whereas the levels of NO, a universal vasodilator, are lower in HAPE-susceptible subjects.¹⁴¹⁻¹⁴³ Bailey and colleagues¹⁴⁴ confirmed lower levels of NO in HAPE subjects at high altitude and also provided evidence of increased free radicals in the pulmonary circulation during HAPE, which might contribute to development of the disorder. Thus, an inherent imbalance of vasoconstrictors (ET-1) and vasodilators (NO) may constitute an important predisposing factor in HAPE-susceptible subjects, an imbalance that provides potential avenues for therapeutic intervention.

Given the central importance of elevated pulmonary artery pressures in the pathogenesis of HAPE, how do these elevated pulmonary artery pressures cause fluid accumulation when patients with severe pulmonary hypertension at sea level do not typically have pulmonary edema? Hultgren¹⁴⁵ has suggested that edema results from uneven hypoxic vasoconstriction, resulting in overperfusion of the microvasculature in areas of the lung where arteriolar vasoconstriction failed to protect downstream vessels. Uneven perfusion is suggested clinically by the typical patchy radiographic appearance (see Fig. 77-9) and by MRI studies in persons breathing hypoxic gas mixtures,¹⁴⁶ which demonstrates greater heterogeneous regional perfusion in HAPE-susceptible subjects.

The leak in overperfusion edema may be due to *capillary stress failure* in which high shear forces cause biomechanical stress and injury in the precapillary arterioles and capillaries.¹⁴⁷ The mechanisms by which high pressures and shear stress lead to a high permeability-type leak may involve a continuum of pressure-related phenomena by which plasma and even red cells move from the intravascular space to the interstitium and subsequently into the alveolar space. At lower levels of pressure elevation, stretch on collagen and other supporting extracellular matrix elements may induce dynamic and quickly reversible changes in barrier permeability,¹⁴⁸ which with greater duration and further pressure elevation, may lead to capillary rupture and alveolar hemorrhage as seen in severe cases of HAPE.

Although the data largely establish a mechanical basis for HAPE, interest in the role of inflammation arose when bronchoalveolar lavage studies in patients with HAPE demonstrated increased cellularity and the presence of chemotactic (leukotriene B₄) and vasoactive (thromboxane B₂) mediators compared to controls.¹³³ Whether the inflammation was a primary or secondary phenomenon was clarified in a study by Swenson and colleagues,¹³² in which bron-

choalveolar lavage was performed in HAPE-susceptible individuals and normal controls within the first 24 hours of arrival at 4559 m, earlier than the lavage samples were obtained in the other studies. At this early time, although the lavage fluid demonstrated high protein and red blood cell content, the levels of which correlated with pulmonary artery pressures measured by echocardiography (Fig. 77-10), there was no evidence of cytokine expression or neutrophil recruitment. These findings solidified the notion

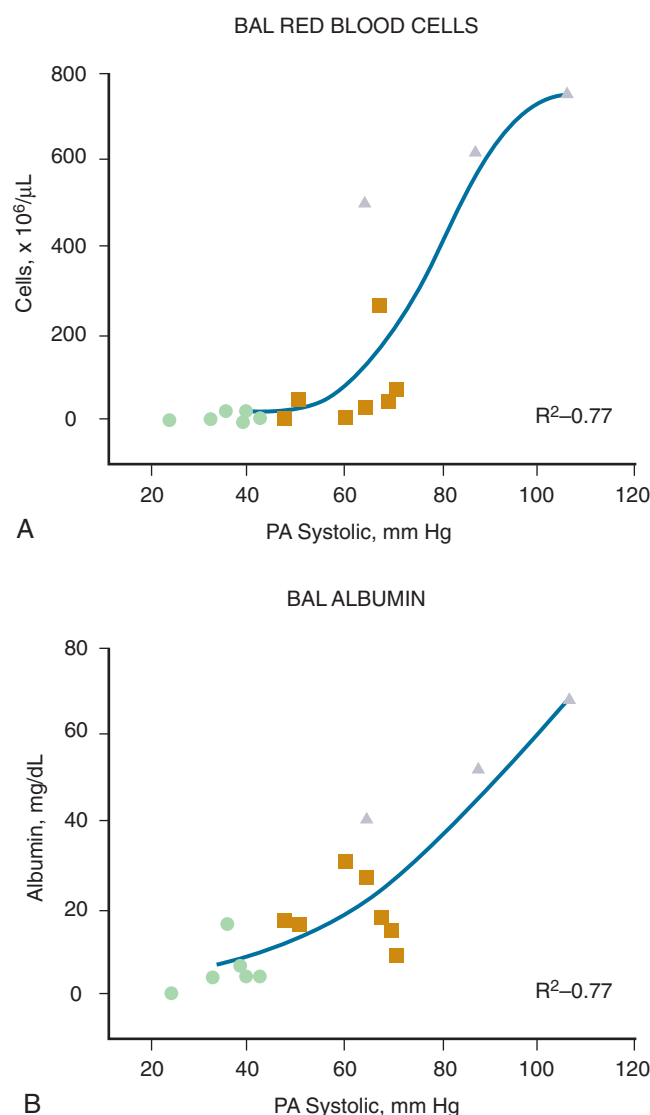

Figure 77-10 The relationship between pulmonary artery pressure (PA) measured by echocardiography and the number of red blood cells and the concentration of albumin in bronchoalveolar lavage (BAL) fluid of normal and HAPE-susceptible individuals at sea level and at 4559 m. The circles in the lower left of both panels show normal values for red blood cells and albumin at low altitude (490 m). Squares indicate HAPE-susceptible individuals at 4559 m who were not experiencing HAPE at the time of bronchoscopy; triangles indicate HAPE-susceptible individuals at 4559 m who were clinically considered to have HAPE at the time of bronchoscopy. Correlation coefficients are provided for the best fit curves of the data at high altitude. (From Swenson ER, Maggiorini M, Mongovin S, et al: Pathogenesis of high-altitude pulmonary edema: inflammation is not an etiologic factor. *J Am Med Assoc* 287:2228–2235, 2002.)

that HAPE starts as a result of high intravascular pressure, not due to an inflammatory process.

Although inflammation is not the primary factor in most cases, it may still play a role in certain situations. Respiratory viral infections have been shown to predispose to HAPE in children,¹⁴⁹ and there are anecdotal reports of viral infections preceding HAPE in adults. This suggests that viral infections may trigger inflammation, which makes the microvascular endothelium more vulnerable to increased pressures. This potential role for upper respiratory tract infections and subsequent inflammation may account for the cases of HAPE seen at surprisingly low altitudes (1500 to 2400 m).¹⁵⁰

Changes in fluid transport dynamics in the lung may also contribute to HAPE. Hypoxia has been shown to decrease alveolar transepithelial sodium transport¹⁵¹ and alveolar fluid clearance,¹⁵² which are known to be important in normal lung fluid balance. In subsequent studies in humans that have examined transepithelial potential differences across the nasal mucosa as a model of alveolar epithelial function, lower transepithelial nasal potentials in normoxia have been demonstrated in HAPE-susceptible individuals versus nonsusceptible controls, which was attributed to decreased sodium transport by the epithelial sodium channel.¹⁵³ A subsequent study confirmed the difference in nasal potential between HAPE-susceptible individuals and controls in normoxia, but could not attribute these differences to alterations in epithelial sodium channel activity.¹⁵⁴ Transalveolar sodium transport can be increased by β_2 -receptor stimulation, and a field study has reported successful prevention of HAPE with inhalation of salmeterol, a long-acting β_2 -agonist.¹⁵³ However, given the multiple actions of this drug, including increased ventilatory response to hypoxia, and tightening of cell-to-cell contacts, the contribution of enhanced alveolar fluid clearance to the study's positive outcome remains uncertain.¹⁵⁵ Finally, ET-1 has been shown to impair alveolar fluid clearance by 65% in a rat model,¹⁵⁶ providing another potential mechanism by which it might contribute to HAPE in humans.

Allemann and colleagues¹⁵⁷ documented an increased incidence of patent foramen ovale in HAPE-susceptible individuals at low and high altitude compared to healthy controls and argued its presence may increase the risk of HAPE. It is not clear, however, whether the patent foramen ovale actually causes HAPE or is a sequela of the prior marked rises in pulmonary artery pressure during sojourns to high altitude or during normoxic exercise seen in HAPE-susceptible individuals.¹⁵⁸

Finally, it has been proposed that HAPE is a form of neurogenic pulmonary edema, in that the presence of red blood cells, the spectrum of serum proteins in HAPE lavage fluid, and the absence of architectural damage are all features seen in this other form of noncardiogenic pulmonary edema.¹⁵⁹ Sympathetically mediated pulmonary venous constriction is thought to play a large role in neurogenic pulmonary edema,¹⁶⁰ while as noted earlier, increased sympathetic activity may play a role in HAPE¹³⁹ and α -adrenergic blockade has been shown to decrease pulmonary artery pressure in HAPE.¹⁶¹ What is lacking in HAPE, however, is the severe neurologic injury typically seen in neurogenic pulmonary edema. Although some HAPE patients have concurrent AMS or HACE, this is usually far less severe than

the profound central nervous system alterations (e.g., subarachnoid hemorrhage) in most cases of neurogenic pulmonary edema.

Prevention. The nonpharmacologic preventive measures previously described for AMS also apply to HAPE, with a slow ascent being the most important strategy. Because unrecognizable subclinical pulmonary edema might be converted to clinical edema by exercise, subjects should avoid overexertion before acclimatization, especially when fatigued. Nifedipine, a calcium channel blocker that attenuates HPV, is effective in preventing HAPE in subjects with a past history of the illness.¹⁶² Because the incidence of HAPE is low, prophylactic nifedipine should be reserved for known susceptible individuals. A single study established that high-dose inhaled salmeterol augments alveolar fluid clearance and may be useful for prophylaxis,¹⁵³ although very high doses (2.5 times those used in asthma management) were used in the study and may be associated with side effects that affect patient tolerance. More recently, Maggiorini and coworkers¹⁶³ demonstrated that tadalafil, a phosphodiesterase inhibitor with pulmonary vasodilatory properties, can also prevent disease in known susceptible individuals. An unexpected finding of this study was that dexamethasone was also effective in this regard. Subsequent studies have established that dexamethasone decreases estimated pulmonary artery pressure following ascent to 4559 m,¹⁶⁴ but because the mechanism of action remains unclear and clinical experience with dexamethasone for HAPE prophylaxis remains limited, it has not become part of standard HAPE prevention protocols.¹¹⁰ Recommended doses for these medications are provided in Table 77-2.

Treatment. Proper treatment depends on the severity of the illness and the immediate setting. For patients in remote locations with limited access to care, the first priority is descent to lower elevation. The patient's level of exertion should be limited during descent because exertion may increase pulmonary artery pressure and worsen the pulmonary edema. If HAPE is diagnosed early, recovery is rapid with descents of only 500 to 1000 m, and the victim may be able to reascend cautiously 2 or 3 days later. If descent is not feasible due to weather or other factors, supplemental oxygen or a portable hyperbaric chamber should be an urgent priority.¹⁶⁵ If neither option is available, positive pressure mask ventilation may improve oxygenation although the effect on outcomes has not been established.¹⁶⁶

Given the reduced margin for error in remote settings, the use of a pulmonary vasodilator such as nifedipine is warranted regardless of whether supplemental oxygen is available. The data supporting this practice are limited, however, and the recommendation is based largely on extensive clinical experience. A single study¹⁶⁷ demonstrated that nifedipine can be used to manage HAPE in the absence of descent or supplemental oxygen but this study was small and lacked a control group. Other pulmonary vasodilators such as tadalafil and sildenafil have not been studied for HAPE treatment but reports in the literature indicate clinicians are using them for this purpose, often in conjunction with calcium channel blocker therapy.¹⁶⁸ Given the absence of data supporting benefit and the risk of

provoking systemic hypotension, concurrent use of two pulmonary vasodilators should be avoided. Such warnings have not been heeded in the field setting,¹⁶⁹ where almost every available pharmacologic modality is often given when most patients, except for the most critically ill, would likely do well with just rest and supplemental oxygen.

In less remote settings such as at ski resorts, treatment with bed rest and oxygen may be sufficient and evacuation to lower elevations may be unnecessary. In well-selected patients with mild disease and adequate support by family or friends to monitor their clinical course, it may even be feasible to send them home or to their hotel with supplemental oxygen rather than evacuating them to a hospital.¹⁷⁰ Complete resolution of the edema may require 24 to 72 hours of oxygen therapy at the altitude of onset whereas moving the patient to a lower altitude results in more rapid improvement. Pulmonary vasodilators can be added in patients who worsen or fail to improve with conservative measures. There are no data comparing nifedipine to phosphodiesterase inhibitors, although there is more clinical experience with the less expensive nifedipine. A single case series documented the use of continuous positive airway pressure to relieve dyspnea in patients with HAPE,¹⁵⁰ but there are no controlled data to suggest this improves outcomes. Because temperatures as high as 38.5°C have been described in HAPE, a finding of elevated temperature should not prompt administration of antibiotics unless the clinical picture is consistent with pneumonia. Patients who do not improve on an appropriate regimen should be investigated for other causes of hypoxemia and lung infiltrates.

PROBLEMS OF HIGH-ALTITUDE RESIDENTS

Chronic Mountain Sickness

First described in Andean dwellers by Monge¹⁷¹ in 1928 and often referred to as Monge disease, *chronic mountain sickness* (CMS) is a commonly described form of chronic altitude illness. It is seen in persons born and living at high altitude as well as in lowlanders who move to high altitudes and stay for prolonged periods of time, generally more than 1 year. Excessive erythrocytosis, defined as a hematocrit above 60% to 70% or more than two standard deviations above the average value for healthy residents at a given high altitude, is an essential characteristic of this syndrome whose severity can be graded based on criteria stipulated in a recent consensus report.¹⁷²

There are geographic and ethnic differences in the prevalence of CMS. It is rarely found in natives of the Tibetan plateau but is frequently encountered in the Andes, in the North American Rockies, and in other mountainous regions where lowlanders have moved as in, for example, Han Chinese who have been relocated to Tibet.¹⁷³⁻¹⁷⁵ The reason for these regional differences is only speculative, but it is thought to be secondary to more advantageous adaptations that the Tibetans have undergone because of their greater duration of existence on the Tibetan plateau compared with that of the Andeans. Especially relevant may be that Tibetans have much less HPV and erythrocytosis compared with other high-altitude populations. These may potentially be markers of more successful adaptation over a much longer period of time.

Clinical Presentation. Symptoms of CMS are similar to those found in persons suffering polycythemia at low altitude: headache, dizziness, lethargy, impaired memory and mentation, and poor sleep. Subsequent investigations reveal cyanosis, plethoric appearance, and elevated hematocrit and hemoglobin. The diagnosis can be established only by eliminating all other causes of polycythemia. Indeed, much confusion in the literature regarding incidence and other aspects of CMS may be due to inadequate validation of the diagnosis. Monge¹⁷¹ and Leon-Velarde and colleagues,¹⁷⁶ for example, noted a high frequency of bronchial complications in patients with CMS, whereas Kryger and coworkers¹⁷³ found evidence of lung disease in 50% of those with CMS in Leadville, Colorado. Indeed, when viewed as a syndrome, it is possible that many cases represent an interaction between some underlying chronic lung disease, high altitude, and, perhaps, heavy metal toxicity.³⁶

Pathophysiology. The likely initiating factors for CMS are a blunted HVR and relative hypoventilation. Hypoventilation increases alveolar hypoxia and arterial hypoxemia. Alveolar hypoxia, in turn, triggers more HPV and greater pulmonary hypertension while arterial hypoxemia leads to increased erythropoietin secretion and more red blood cell production.^{173,177,178} With exercise, rapid interstitial fluid accumulation has also been noted in patients in CMS,¹⁷⁹ which may also contribute to hypoxemia.

The precise cause and effect relationships between hypoventilation, polycythemia, and CMS are not entirely clear, however. For example, polycythemia has been shown to blunt ventilatory responses,^{180,181} while hypoxia itself may contribute to the ventilatory depression, as evidenced by an increase in ventilation in some natives with CMS when given supplemental oxygen. It should also be noted that HPV may not solely be a function of increased alveolar hypoxia because patients with CMS also have been noted to have accentuated pulmonary artery pressure responses to modest exercise when compared with healthy individuals living at the same elevation,¹⁸² a phenomenon also seen in HAPE-susceptible patients as noted earlier.

While the excessive polycythemia of CMS is likely due to greater hypoxemia, the actual hematocrit is often higher than expected for the measured arterial SO_2 ,¹⁸³ suggesting that affected individuals may have exaggerated erythropoietic responses to a given hypoxic stimulus.¹⁷⁷ Severe nocturnal desaturation also may contribute to the development of polycythemia, as suggested by investigations in the Rocky Mountains that revealed greater hypoxemia during sleep in patients with CMS than in healthy controls.¹⁸⁴ Finally, Jefferson and coworkers³⁶ found that a majority of subjects with CMS and excessive erythrocytosis in an Andean mining community had detectable serum concentrations of cobalt, a heavy metal known to stimulate renal erythropoietin production. This may help explain the higher incidence of CMS in high-altitude regions where mining is common.

Once present, polycythemia may also contribute to the pulmonary vascular issues noted earlier, because the increase in viscosity leads to increased pulmonary vascular resistance. Along with impairments in gas exchange and pulmonary vascular changes resulting from HPV, the onset

of polycythemia represents a turning point in CMS that ultimately leads to the clinical deterioration and demise of these patients.^{175,185}

Treatment. The key to treating CMS is to decrease the red cell mass. Improving oxygenation and thereby reducing the hypoxic stimulus for red blood cell production is the most physiologic approach to achieving this goal. Although relocation to a lower altitude is the definitive means to achieve these goals, this approach is not acceptable for many patients and other treatments are often employed. Phlebotomy has long been used, but despite the common practice and prompt subjective improvement, long-term benefits have not been well documented. Low-flow oxygen during sleep is probably effective, especially for those with marked sleep desaturation. Older data suggest that, by virtue of its ability to stimulate ventilation and increase alveolar PO₂, medroxyprogesterone, may be effective at decreasing hematocrit and treating CMS,¹⁸⁶ while more recent data indicate acetazolamide is an inexpensive, safe, and effective intervention.¹⁸⁷ Daily use of angiotensin-converting enzyme inhibitors can also suppress erythropoietin secretion and decrease the need for phlebotomy.¹⁸⁸

High-Altitude Pulmonary Hypertension

An alternative form of altitude-related disease in long-term residents has now been described in areas outside the Andes Mountains. Referred to as high-altitude pulmonary hypertension, it is marked by pulmonary hypertension and cor pulmonale *without* polycythemia. According to a recent consensus panel,¹⁷² high-altitude pulmonary hypertension is present if a resident at altitudes above 2500 m has a mean pulmonary artery pressure greater than 30 mm Hg or a systolic pulmonary artery pressure greater than 50 mm Hg, right ventricular hypertrophy, right heart failure, and moderate hypoxemia without excessive erythrocytosis (hemoglobin less than 21 g/dL in men and less than 19 g/dL in women). There is considerable overlap between this disease and subacute mountain sickness, a syndrome of pulmonary hypertension and right heart failure seen in lowlanders after weeks to months at high altitude,¹⁸⁹ with the major difference being the time spent at high altitude by the affected individual. There is also some debate as to whether this truly represents a separate entity from CMS or is simply a variant of the same disease.¹⁷⁸

Affected individuals present with dyspnea, cough, cyanosis, peripheral edema, and physical examination findings consistent with right heart failure. Right axis deviation, right ventricular hypertrophy, and P-pulmonale may be present on the electrocardiogram while chest imaging reveals right ventricular and right atrial enlargement and prominence of the pulmonary arteries.¹⁷² The pulmonary hemodynamics are similar to those seen in patients with CMS.¹⁷⁸ The optimal treatment for the disorder is relocation to lower elevation but, as in CMS, descent may not be feasible and pharmacologic options may be necessary. Unfortunately, aside from a small placebo-controlled trial that demonstrated that a 3-month course of the phosphodiesterase inhibitor sildenafil lowered pulmonary artery pressure by a modest amount (approximately 6 to 7 mm Hg)

and improved 6-minute walk distance,¹⁹⁰ larger studies of this and other pulmonary vasodilators are lacking. No formal treatment protocols exist at this time.

Reentry Pulmonary Edema

Some persons living for years at high altitude who descend to lower altitudes may develop HAPE on reascent. The phenomenon has been most often observed in Peru, where, due to the ease of air travel, high-altitude residents can return from sea level to high altitude quite rapidly. Cases have also been reported in Leadville, Colorado, but reports are conspicuously absent from Nepal and Tibet, possibly because rapid return to high altitude is often less readily available. Authors have suggested that the incidence of HAPE on reascent may be higher than during initial ascent by sojourners,¹⁹¹ but data on true incidence are lacking; children and adolescents may be more susceptible than adults.¹⁹¹ It has been postulated that the increased muscularization of pulmonary arterioles that develops with chronic high-altitude exposure generates an inordinately high pulmonary artery pressure on reascent, causing the edema. Aside from a study by Marticorena and Hultgren,¹⁹² which demonstrated that treatment with bed rest alone may be sufficient in mild to moderate cases, no treatment trials have been conducted for reentry HAPE and the disorder should be managed in the same way as for HAPE in unacclimatized lowlanders.

PREEXISTING ILLNESS AND HIGH ALTITUDE

Given the prevalence of many common diseases, such as hypertension and *chronic obstructive pulmonary disease* (COPD) in the general population, it is likely that many high-altitude travelers have some underlying medical condition. This situation raises two important questions: (1) Will the underlying disease predispose these individuals to high-altitude illness? (2) Will the added stress of hypoxia at high altitude worsen control of their underlying problems? To date, few studies have examined what happens to people with respiratory and other diseases when they visit high-altitude destinations, and even fewer data are available about how to treat them before and after their exposure. Several major categories of respiratory diseases are discussed in following paragraphs, while other major disease categories including heart disease,¹⁹³ renal disease,¹⁹⁴ and diabetes¹⁹⁵ are reviewed elsewhere.

RESPIRATORY DISEASES

High-altitude exposure poses several challenges to patients with lung disease that have been reviewed extensively elsewhere.¹⁹⁶ Several major forms of lung disease are considered in brief here.

Chronic Obstructive Pulmonary Disease and Interstitial Lung Disease

The drop in barometric pressure and subsequent fall in inspired PO₂ place patients with severe COPD and interstitial

lung disease at risk for arterial desaturation, particularly with exertion. Patients with moderate to severe COPD ($FEV_1 < 1.5$ L) and interstitial lung disease should undergo pre-travel assessment of their risk for hypoxemia and need for supplemental oxygen using one of several possible strategies, including prediction rules that take into account arterial blood gases^{197,198} and pulmonary function testing at sea level, cardiopulmonary exercise testing,¹⁹⁹ or exposure to simulated hypoxic conditions using the hypoxia altitude simulation test.²⁰⁰ For patients in whom the predicted value of arterial PO_2 falls below 50 mm Hg—the same threshold used for determining supplemental oxygen needs on commercial air flight—home oxygen should be prescribed and the prescription filled at the patient's destination (e.g., a ski resort town). An alternative strategy in patients with less severe disease is to have them monitor their own pulse oximetry using a portable handheld device with instruction to have a prewritten home oxygen prescription filled if their saturation falls below certain thresholds.²⁰¹ Patients with COPD should travel with their controller medications and a supply of rescue medications in case their condition is exacerbated. Because safety of patients with COPD or interstitial lung disease sleeping at altitude above 3000 m is unknown, such patients should sleep at elevations lower than 3000 m.

Asthma

Changes in air temperature, humidity, and density may alter lung mechanics and airflow obstruction in patients with asthma, but field data demonstrate that mild, well-controlled asthmatic patients have decreased bronchial responsiveness at elevations as high as 5000 m²⁰² and tolerate ascents as high as 6410 m without significant changes in their symptoms.^{203,204} Patients must have their asthma under good control before any trip to high altitude and should travel with both their controller medications and an adequate supply of rescue inhalers and prednisone for use in case of an exacerbation.

Pulmonary Vascular Disease

In patients with pulmonary hypertension, low alveolar oxygen tensions provoke HPV and increase pulmonary artery pressure, which in turn may lead to either acute right heart failure or HAPE. No systematic studies have examined this issue but several case reports and case series have documented HAPE in patients with pulmonary hypertension secondary to anatomic or nonanatomic causes.²⁰⁵ Patients with known or suspected pulmonary hypertension should undergo echocardiography to measure pulmonary artery pressures. Travel to high altitude should be avoided in patients with moderate to severe disease, although the threshold used to proscribe travel is not clear. The available evidence suggests that mean pulmonary artery pressures of about 40 mm Hg are sufficient to increase the incidence of HAPE but a wide range of pressures have been documented in case reports of this phenomenon at high altitude.²⁰⁵ Patients with less severe disease should use nifedipine and should be encouraged to monitor their pulse oximetry using either a handheld device or by periodically visiting a local clinic. Patients with congenital absence of a pulmonary artery should also avoid high-altitude travel, because these

individuals are known to be susceptible to HAPE.²⁰⁶ Whether the same risks are present in patients following pneumonectomy has not been established but the prudent course is for such patients to avoid high-altitude exposure as well.

Sleep Apnea

Although the decrease in barometric pressure and air density at high altitude might lead one to expect a decrease in the severity of obstructive sleep apnea in this environment, recent field studies suggest that obstructive sleep apnea persists following ascent to 2950 m and is accompanied by a marked increase in the number of central apneas as well as impaired performance on simulated driving tasks, increased systolic blood pressure, and more frequent cardiac arrhythmias.²⁰⁷ Given these issues, it would be prudent for people with moderate to severe obstructive sleep apnea to travel to high altitude with their continuous positive airway pressure machine, assuming that reliable access to power sources can be arranged. If logistical issues prevent the use of continuous positive airway pressure, acetazolamide (250 mg twice daily) can decrease the apnea-hypopnea index, improve sleep efficiency and subjective insomnia, and blunt the rise in systolic pressure during sleep at altitudes as high as 2590 m.²⁰⁸

Thromboembolic Disease

Although many case reports document arterial or venous thromboembolic events at high altitude, a review of the cases reveals that most events were reported in people with underlying coagulopathy.¹⁹⁶ There remains no compelling evidence that the risk of thromboembolism is increased in normal individuals at high altitude. As a result, there is no need to screen for thrombophilia in asymptomatic persons before high-altitude travel and no indication to start anticoagulation in those not previously on such medication. Efforts should be made to maintain mobility and good hydration throughout the trip. The international normalized ratio may change with trips to and from altitude,²⁰⁹ and patients on warfarin should consider obtaining follow-up international normalized ratio values upon returning from a long sojourn or periodically during prolonged stays at a new altitude.

ALTITUDE-ILLNESS MEDICATIONS AND UNDERLYING MEDICAL DISEASES

As noted earlier, acetazolamide, dexamethasone, nifedipine, and the phosphodiesterase inhibitors play a large role in the prevention and treatment of high-altitude illness. The efficacy and safety of these medications has largely been established on the basis of studies in healthy individuals with no underlying medical disease. However, given the increasing numbers of people traveling to high altitude, it is possible that many of those using these medications for management of altitude illness will have underlying medical problems or will be using other medications that cause adverse drug interactions. Practical guidelines for the selection and dosing of the altitude illness medications in such patient populations are reviewed elsewhere²¹⁰ and are summarized in Table 77-2.

Key Points

- At every step of the oxygen transport chain, important adaptations maintain oxygen delivery in the setting of lower ambient oxygen levels. However, the magnitude of these changes varies between individuals and affects individual tolerance of this environment.
- Various aspects of sleep, including respiratory patterns, sleep architecture, and subjective impressions of sleep quality, are altered and contribute to poor sleep at high altitude.
- Maximum exercise capacity is reduced at high altitude and does not recover to sea-level baseline values even with prolonged time and acclimatization at high altitude.
- An overly rapid ascent to high elevation is the primary reason acute altitude illness develops, and a gradual ascent is the best nonpharmacologic means for prevention.
- Acute mountain sickness is the most common form of acute altitude illness and is marked by the onset of headache plus one or more other symptoms, including lightheadedness, gastrointestinal upset, fatigue, and poor sleep several hours following ascent to high altitude.
- High-altitude cerebral edema and high-altitude pulmonary edema are uncommon forms of severe acute altitude illness in which mortality is possible but avoidable with prompt recognition and initiation of treatment.
- Long-term high-altitude residents are generally not susceptible to acute forms of high-altitude illness but are at risk for two forms of chronic altitude illness, namely chronic mountain sickness and high-altitude

pulmonary hypertension, for which the optimal form of treatment is relocation to lower elevation.

- High-altitude travelers with underlying medical problems should undergo pretravel assessment to evaluate whether the underlying disease process may be worse at high altitude. The choice and dose of prophylactic medications may require adjustment based on the patient's underlying medical issues.

INTRODUCTION

Diving and work in compressed air have produced occupational exposure to hazardous environments for over 100 years. In the past 60 years, diving has become a recreation for millions of individuals throughout the world. Any physician may encounter a recreational diver for an illness related to a diving exposure or for medical clearance for diving. Occasionally a physician may be confronted with an acute medical emergency related to diving exposure, such as decompression sickness, arterial gas embolism, or drowning. This chapter provides a basis for initiating treatment, seeking consultation, or furthering education in this interesting area of environmental medicine.

INCREASED PRESSURE

Underwater exposure results in increasing pressure directly proportional to depth (Table 78-1). There is also exposure to pressure in hyperbaric chambers, pressurized tunnels and caissons used for underwater construction, and underwater habitats. As depth increases, the diver breathes gas of increased density using breathing equipment that provides oxygen and allows for elimination of carbon dioxide. Increased depth and pressure also lead to decreases in gas volume and an increased amount of gas dissolved in body tissues. The terms *atmosphere* (ATM) and *atmosphere absolute* (ATA) both refer to pressure; ATM, however, can be used as a relative term (33 feet of water depth is equivalent to 1 ATM of water), whereas ATA is always used for absolute pressure (33 feet of water depth is equivalent to 2 ATA). ATA is the term used in this chapter and is always used for equations, such as Boyle's law.

WATER IMMERSION

Intrathoracic blood volume increases with water immersion.¹ Increased hydrostatic pressure during immersion prevents blood from pooling in the peripheral veins,

increases transdiaphragmatic pressure, and increases venous return.^{2,3} The magnitude of the increase in intrathoracic blood volume during immersion with the head above water has been estimated to be 700 mL.² The central blood shifts result in an increase in cardiac output² and an increase in central venous pressure. The increase in intrathoracic blood volume causes a diuresis because of release of natriuretic hormones and suppression of antidiuretic hormone.

THERMAL EXPOSURE

Most diving takes place in water colder than skin temperature, and the diver loses heat throughout the dive. Hypothermia happens rapidly in the absence of protective garments even in relatively warm water (e.g., 22° to 23° C). Cold stress evokes thermogenic responses, reflected by a rise in *oxygen consumption* ($\dot{V}O_2$) upon exposure to cold water to generate additional body heat and minimize core temperature change. Cold water diving also leads to peripheral vasoconstriction; the magnitude of the vasoconstriction is dependent on body core temperature, which, in turn, is affected by the amount of thermal protection and the water temperature. Heat loss is inhibited in divers doing moderate work in water above 30° C, and, in this situation, hyperthermia can develop.

ENERGY NEEDS FOR DIVING

A scuba (*self-contained underwater breathing apparatus*) diver swimming underwater at a speed of 1.0 knot (about 100 feet/min or 1.15 miles per hour or 1.85 km per mile) consumes about 25 mL of oxygen per kilogram per minute (Fig. 78-1).^{4,5} A diver with a maximum $\dot{V}O_2$ of 40 mL/kg per minute would tolerate swimming at 1.3 knots for a few minutes but would become extremely tachypneic to compensate for lactate production. For a diver with a maximum $\dot{V}O_2$ of 40 mL/kg per minute, sustainable swimming speed, working at 50% of maximum capacity, would be about

Table 78-1 Pressure Equivalents for Altitude and Depth

	Feet	ATA	mm Hg	psi
Altitude above sea level	12,000	0.636	483	9.3
	8000	0.742	564	10.9
	4000	0.863	656	12.7
Sea level	0	1	760	14.7
Depth in seawater	33	2	1520	29.4
	66	3	2280	44.1
	99	4	3040	58.8
	132	5	3800	73.5

ATA, atmosphere absolute; psi, pounds per square inch.

Figure 78-1 Oxygen consumption and metabolic equivalents (METs) are shown for underwater swimming. The speed is shown in knots; one knot is one nautical mile per hour. One knot = 100 feet per min = 1.15 miles per hr = 1.85 km per hr. (Data from Navy Department: *U.S. Navy diving manual*, vol 1, rev 3: Air diving. Publication No. NAVSEA 0994-LP-001-9110. Washington, DC, 1996, U.S. Navy Department.)

0.9 knots or 90 feet/min, whereas the diver with a maximum $\dot{V}O_2$ of 25 mL/kg per minute would be able to sustain a swimming speed of only approximately 0.55 knots or 55 feet/min. Safety considerations suggest that the sport diver should be able to tolerate a sustained workload of about 20 mL/kg per minute (50% of maximum).^{4,5} Poorly conditioned divers can experience severe dyspnea under even mildly stressful conditions that exceed their anaerobic threshold.

EQUIPMENT

OPEN-CIRCUIT SCUBA

The most commonly used breathing equipment in diving is the open-circuit scuba. This equipment (Fig. 78-2) consists of a metal cylinder containing compressed air connected to a pressure regulator that lowers pressure to ambient pressure. This device delivers ambient-pressure air only when inhalation is initiated and allows flow that matches the minute volume of the diver. Expired air is released directly into the surrounding water. A typical scuba cylinder can supply approximately 2100 L of air at the surface (1 ATA). This volume is reduced in direct proportion to ambient pressure. For example, at a depth of 66 feet of seawater or 3 ATA pressure, the effective volume of air is decreased to 700 L. With a minute ventilation of 20 L/min, this air

OPEN-CIRCUIT SCUBA

CLOSED-CIRCUIT REBREATHING

Figure 78-2 Two types of self-contained diving systems. The open-circuit scuba is the system commonly used for recreational diving. Air is exhaled into the surrounding water. Rebreather systems allow exhaled breathing gas to be recycled through a carbon dioxide scrubber, mixed with additional breathing gas, and returned to the diver through a breathing bag. Breathing gas is replenished via a demand valve. This system can be used with 100% oxygen or oxygen-enriched air mixtures. Other forms of rebreather systems contain separate oxygen and inert gas supplies, and mixing is controlled with a small computer to maintain a constant oxygen partial pressure.

supply would last 105 minutes at the surface but only 35 minutes at 66 feet of seawater. Open-circuit scuba is usually limited to depths above 200 feet because of limited air supply, nitrogen narcosis, and oxygen toxicity.

CLOSED-CIRCUIT REBREATHING SCUBA

The self-contained rebreather uses a carbon dioxide absorbent to remove exhaled carbon dioxide and replenishes only the oxygen used. Inert gas is conserved by recycling the exhaled gas through the carbon dioxide absorbent and then adding oxygen before the gas is rebreathed (see Fig. 78-2). Little gas is released into the surrounding water, oxygen can be carried in volumes adequate for several hours of exposure, and gas consumption is independent of depth. Although use of closed-circuit scuba in the past was confined to commercial and military divers, such systems now are becoming popular among recreational divers.

SURFACE-SUPPLIED EQUIPMENT

Commercial diving often employs this form of equipment. The diver breathes compressed air or other gas mixtures pumped from the surface to the helmet. The diving helmet is attached at the collar to a diving suit so that air flows from the helmet into the suit to maintain an air layer for thermal protection. Modern systems contain a demand mask built into the helmet.

DISORDERS RELATED TO DIVING: NOMENCLATURE

Golding and coworkers⁶ described disorders related to supersaturation of inert gases in tissues with subsequent bubble formation as *decompression sickness* (DCS). They

described a systemic form of DCS that involves the central nervous system, the lungs, and the circulation (“serious,” type II) and a nonsystemic (peripheral) form that involves the skin, bones, and joints (“minor,” type I). *Arterial gas embolism* is named separately based on its relationship to pulmonary barotrauma. Francis and Smith⁷ suggested the term *decompression illness* for these two disorders because they can be clinically difficult to separate and require similar therapy.

PRESSURE EFFECTS: BOYLE’S LAW

RELATION OF GAS VOLUME TO DEPTH

Boyle’s law states that, if the temperature of a fixed mass of an ideal gas is kept constant, volume and pressure are inversely related. Consequently, when the pressure is doubled, the volume is reduced to one half of the original volume. Because the gas volume is proportional to the absolute pressure, the volume change from the surface to 33 feet of seawater (from 1 to 2 ATA) is greater than the change from 33 to 66 feet (from 2 to 3 ATA).

BAROTRAUMA

With increased pressure, volume in the lungs, middle ear, paranasal sinuses, and gastrointestinal tract are reduced. Displacement of tissues into the diminishing volume of these spaces may cause tissue injury and dysfunction of the organ involved. Barotrauma can affect a paranasal sinus with an occluded orifice, a residual air pocket left between a tooth filling and the base of the tooth, or the air space within a diving mask.

Pulmonary Barotrauma and Arterial Gas Embolism

The gas a diver breathes is pressurized to the ambient pressure so that pressure gradients from the breathing supply to the airways are not altered as the diver descends. Behnke⁸ and Polak and Adams⁹ described lung barotrauma in ascending divers due to inadequate exhalation during ascent and overexpansion of the lungs. Later studies provided further insight into mechanisms and prevention of pulmonary barotrauma.¹⁰ After breathing compressed air, persons who ascend to the surface from depths as shallow as 4 feet can experience pulmonary barotrauma.

Pathophysiology. Under experimental conditions, transpulmonary pressures (i.e., the difference between intratracheal and intrapleural pressures) of 95 to 110 cm H₂O are sufficient to disrupt the pulmonary parenchyma and force gas into the interstitium.¹⁰ Extra-alveolar gas will migrate through perivascular sheaths to cause mediastinal emphysema and pneumothorax.¹⁰ Gas can also dissect into the retroperitoneum and into the subcutaneous tissues of the neck. Extra-alveolar gas can pass into ruptured blood vessels, travel to the left side of the heart, and enter the arterial circulation as gaseous emboli. The dissemination of gas bubbles throughout the arterial circulation causes injury to other organ systems and to skeletal muscle, which is evident by a rise in serum creatine kinase level.¹¹

Figure 78-3 Chest radiograph from a diver who experienced near drowning. The diffuse pulmonary edema pattern is suggestive of water aspiration.

Pulmonary barotrauma can be seen in divers who would not be considered at risk for lung overpressure. Occult lung disease may contribute to unexplained barotrauma and cerebral air embolism.¹² Epidemiologic studies have not demonstrated a significant relationship between asthma and an increased risk for pulmonary barotrauma.¹³

Clinical Manifestations of Arterial Gas Embolism.

The brain is commonly involved. Within minutes of surfacing, the diver can experience loss of consciousness, hemiplegia, stupor, and confusion. Seizures, vertigo, visual disturbances, sensory changes, headache, and circulatory collapse are common. Most individuals fully recover if they are promptly recompressed.¹⁴

When they lose consciousness in the water, victims of arterial gas embolism frequently drown. Chest radiographs (Fig. 78-3) may show a diffuse lung edema pattern. About 5% of patients immediately develop apnea, unconsciousness, and cardiac arrest. This catastrophic course results from filling of the heart and great vessels with air. Many of these individuals are unresponsive to cardiopulmonary resuscitation and advanced life support measures.¹⁵ A report of 31 patients with cerebral air embolism from diving included the following findings: 25% demonstrated pneumomediastinum; 10%, subcutaneous emphysema; 6%, pneumocardium; 3%, pneumoperitoneum; and 3%, pneumothorax. Fifty-two percent had pulmonary opacities indicating associated drowning.¹⁶

Mediastinal emphysema is generally associated with mild substernal pain that may be exacerbated by inspiration, coughing, or swallowing. Unless massive, this condition is not usually associated with circulatory compromise. On physical examination a crunching sound synchronous with cardiac action may be auscultated (the Hamman sign). The chest radiograph confirms the diagnosis. No treatment is usually necessary.

Subcutaneous emphysema causes swelling and crepitus in the base of the neck and supraclavicular fossa, sore throat, hoarseness, and dysphagia. Radiographs may be helpful in detecting subtle cases, but *computed tomography* (CT) scans are more sensitive and can be useful to confirm the diagnosis of barotrauma in doubtful cases. Extra-alveolar gas that ruptures into the pleural space will cause a pneumothorax. Laboratory evaluation may show an elevated hematocrit level and elevation of several serum enzyme levels.¹⁷ Treatment for arterial gas embolism requires recompression in a hyperbaric chamber (see later).

Middle Ear Barotrauma

Middle ear barotrauma is the most common diving-related disorder encountered in divers.¹⁸ The middle ear undergoes barotrauma when the eustachian tube is blocked during descent and the middle ear space cannot equilibrate with the increasing ambient pressure. The tympanic membrane is displaced inward and may rupture. The middle ear may fill with blood from engorged mucous membranes. Infection and hearing loss are complications. Symptoms during descent include pain in the affected ear that increases with depth. Relief of pain without proper equalization of the middle ear pressure usually indicates that the tympanic membrane has ruptured. Cold water entering the middle ear when the tympanic membrane ruptures may cause vertigo because of unilateral vestibular stimulation. Late complications include bacterial otitis media, serous otitis media, and chronic tympanic membrane perforation.¹⁸ In rare cases of middle ear barotrauma, the facial nerve is injured by the increased pressure and a temporary facial paralysis results.¹⁹ A modified Valsalva maneuver is commonly used to equilibrate middle ear pressure. Because middle ear barotrauma causes edema and hemorrhage in the middle ear, equalization is usually impossible to achieve until healing is complete. The presence of middle ear barotrauma usually prohibits diving until it is resolved.

Alternobaric Vertigo. Vertigo may develop on ascent when the reduction of middle ear pressure is not uniform in both ears. The pressure imbalance causes differential stimulation of the labyrinths, resulting in what is called *alternobaric vertigo*. The sensation of vertigo may persist for 1 to 2 hours after diving and gradually disappears without therapy. Symptoms are similar to labyrinthitis and can include nausea, vomiting, and generalized malaise. Some subjects may be particularly susceptible to alternobaric vertigo if they have had previous injury or infection of the labyrinths. In susceptible individuals, use of moderate doses of antihistamines or decongestants may prevent symptoms. The disorder must be differentiated from vestibular DCS, which is usually associated with deeper, prolonged diving.

Inner Ear Barotrauma

Inner ear barotrauma may develop on descent in divers who perform a forceful Valsalva maneuver to equalize middle ear pressure. When the eustachian tube is blocked, middle ear pressure becomes progressively more negative relative to ambient pressure.^{18,20} When a Valsalva maneuver is then performed, intrathoracic pressure, central venous pressure, spinal fluid pressure, and inner ear pressure rise above ambient pressure, thereby increasing the

gradient between the inner ear perilymph and the middle ear. The round or oval window can rupture, and perilymph can then leak from the inner ear to the middle ear.

Symptoms include vertigo, nausea, vomiting, tinnitus, and loss of hearing on the affected side. Severity may vary, and some divers complain of hearing loss, tinnitus, or vertigo only after diving.

Treatment varies from conservative therapy to surgical repair of the round or oval window. Vertigo and nausea can be treated with benzodiazepine medications. Tinnitus and reduced hearing may become chronic, particularly if no treatment is provided. Divers who exhibit clinical evidence of inner ear barotrauma with intact round and oval windows may have a pressure injury to the organ of Corti and the vestibular system.²¹

Inner ear DCS may be seen within 2 hours of surfacing and may include vertigo and hearing loss.²² The mechanism is poorly understood but may involve formation of bubbles in the inner ear or embolism of systemic bubbles. Divers with inner ear DCS have been reported to have a higher prevalence of *patent foramen ovale* (PFO), a condition that increases risk for right to left shunts of air bubbles and thus of decompression events; such an association suggests that the inner ear DCS may also result from air emboli.^{23,24} The proper therapy for inner ear DCS is hyperbaric recompression.

Sinus Barotrauma

When a sinus orifice is occluded, pressure within the sinus becomes negative with respect to ambient pressure, and mucosal blood vessels become engorged and eventually rupture. Pain over the affected sinus during descent and epistaxis on ascent are usual symptoms. Headache following a dive may indicate sphenoid sinus barotrauma. Treatment includes decongestants and maneuvers to drain the affected sinus. Persistence of blood in the sinus may result in bacterial sinusitis. Prevention is accomplished by avoiding diving with congestion of the nasopharynx and prudent use of decongestants. If a maxillary sinus orifice is occluded, the maxillary branch of the trigeminal nerve may be compressed during ascent and result in infraorbital paresthesias that usually resolve in 2 to 3 hours.²⁵

Less Common Forms of Barotrauma

Facial barotrauma (mask squeeze) happens in the area of distribution of the diving mask. Facial edema, ecchymoses, and conjunctival hemorrhages can be noted after diving. Retro-orbital hematoma and diplopia have been described as complications.^{26,27} The disorder is self-limiting; no treatment is needed.

Tooth barotrauma leading to severe toothache results when air pockets under fillings or in areas of decay become compressed on descent. Careful dental work prevents this disorder.²⁸

Gastrointestinal barotrauma results when air enters the stomach during diving due to faulty breathing apparatus or by air swallowing. On ascent the expanding air will distend the stomach or intestine. Gastric distention can occlude the esophageal-gastric junction and prevent eructation. Distention of the stomach may cause stomach rupture and pneumoperitoneum.²⁹ The diver experiences abdominal pain, which increases during ascent. Treatment

Table 78-2 Characteristics of Inert Gases*

Gas	Molecular Weight	Lipid Solubility [†]	Water Solubility	Narcotic Potential [‡]
Helium	4	0.015	0.009	0.23
Neon	20	0.019	0.009	0.28
Hydrogen	2	0.036	0.018	0.55
Nitrogen	28	0.067	0.013	1.00
Argon	40	0.140	0.026	2.32

*Solubility of the various gases in lipid is related to their narcotic potential.

Helium is the least, and argon the most, narcotic gas in the list.

[†]Expressed as gas volume/solute volume at 1 bar.

[‡]Values relative to nitrogen.

Adapted from Bennett PB: Inert gas narcosis and HPNS. In Bove AA, editor: *Bove and Davis' diving medicine*, ed 4, Philadelphia, 2004, WB Saunders, pp 225–240.

requires surgical repair of the ruptured viscus. Divers with previous gastric surgery may be prone to gastric air trapping.³⁰

DISSOLVED INERT GAS EFFECTS: HENRY'S LAW

INERT GAS KINETICS

Gases dissolve in tissues, fats, and water according to Henry's law: $Q = c \cdot P$, where c , a solubility coefficient, and P , the partial pressure of the gas, determine the quantity (Q) of dissolved inert gas. Increased ambient pressure increases dissolved gas concentration in the tissues. The partial pressure of the gas and the solubility of the gas in the specific tissue (Table 78-2) determine dissolved gas content. Although Henry's law determines the amount of gas in the tissue, there is a finite time required for equilibrium to be achieved. Factors that affect the rate of entry include blood flow and the rate of diffusion of gases into the tissue. Tissue gas concentration follows an asymptotic curve in which the tissue gas concentration approaches the maximum concentration for the given pressure after time has elapsed. Similar kinetics control the washout of inert gas from tissues when ambient pressure is reduced. Different body compartments have different gas exchange characteristics.³¹

Because most diving is of short duration (i.e., minutes to hours) and shallow (i.e., in depths shallower than 200 feet), only a few tissue compartments reach equilibrium based on Henry's law. Divers can return to the surface from these short-duration dives by following a schedule of ascent based on depth and time.³¹ When diving exposure is long enough, all tissues reach equilibrium at the new ambient pressure and are fully saturated with inert gas. Divers can spend prolonged periods (weeks) under pressure, with all tissues saturated at the increased pressure, without serious physiologic changes.³²

INERT GAS SUPERSATURATION IN TISSUES

When the diver ascends after breathing pressurized gas, tissues become supersaturated with gas. When the degree

of supersaturation becomes excessive, dissolved gas will leave solution and form free gas. Recent studies suggest that blood microparticles may act as a nidus for bubble formation in blood.³³

DECOMPRESSION SICKNESS

Excess supersaturation causes dissolved gases to change phase to the gaseous form.³⁴ Expansion of gases in blood and tissues on ascent results in damage and dysfunction of tissues and organs and venous gas embolism to the lungs. DCS is the disorder caused by damage to organs and tissues as a result of free gas production.

Bert³⁵ first described the pathophysiology of DCS. Subsequent investigators in the early twentieth century concluded from autopsies on divers and caisson workers that DCS is caused by free gas in blood and tissues.³⁶ Based on free gas volume and location, they were able to explain the variety and severity of the symptoms. Paralysis resulted from free gas in the spinal cord, cerebral dysfunction was thought to result from free gas in the brain, and dyspnea was associated with free gas in the pulmonary circulation. Muscle and joint pain may be due to free gas in ligaments, fascia, periosteum, marrow, or nerve sheaths.

Hallenbeck and colleagues³⁷ described effects of free gas in blood and tissues that were not caused by mechanical obstruction. Subsequent studies identified clotting and platelet activation, intravascular coagulation, plasma leakage from the intravascular space, hemoconcentration, and hypovolemia as manifestations of surface effects of the bubbles.³⁸ Venous gas emboli are commonly present before overt symptoms of DCS appear.³⁹ Free gas and tissue injury result in activation of the inflammatory cascade.⁴⁰ The inflammatory response causes fluid to leak into the interstitial tissues of the systemic and pulmonary vascular beds.⁴¹

Factors Affecting Risk for Decompression Sickness

The use of ultrasonography for intravascular bubble detection has provided insight into the presence of bubbles following diving.⁴² Many divers demonstrate venous gas emboli but no manifestations of DCS. The concept of a threshold or dose-response effect has been postulated, wherein a certain volume of free gas is needed to produce the clinical disorder and lesser amounts are asymptomatic.⁴³ Venous bubbles in asymptomatic divers and aviators are associated with increased risk for developing DCS after diving or altitude exposure.^{44,45} Exercise and temperature during decompression are considered to be risk factors for DCS. Breath-hold divers can develop DCS from frequent repetitive dives.^{45a}

Symptoms can be prevented by keeping the degree of supersaturation below a certain level.⁴⁶ The concept of a critical pressure ratio is the basis for most decompression tables used to prevent DCS. The body can be considered as a set of tissue compartments with different rates of gas uptake and elimination.⁴⁶ Although these tissues do not represent discrete anatomic structures, they provide a convenient means for understanding the kinetics of inert gas exchange. In most decompression schedules, stops during ascent are selected to avoid excess supersaturation in tissues with specific gas-exchange rates (Fig. 78-4). Decompression procedures are well defined for air and other mixtures of

Figure 78-4 Theoretical nitrogen gas concentrations are expressed in units of pressure for an exposure of 75 psi (5.1 ATA) following the depth-time profile indicated by the heavy line. Curves are shown for five theoretical tissue compartments with different rates of gas exchange. Gas concentrations increase to different levels in the different tissue compartments during exposure to pressure. When pressure is reduced, gas concentrations in the different tissue compartments fall at different rates. Stops during return to baseline allow tissue concentration to fall to a safe level of supersaturation before reducing pressure further. (Data from Boycott AE, Damant GCC, Haldane J: The prevention of compressed air illness. *J Hyg [Cambridge]* 8:342–443, 1908.)

nitrogen and oxygen; helium and oxygen; nitrogen, helium, and oxygen (trimix); hydrogen and oxygen; and a few rare earth gases such as argon and neon.

Patent Foramen Ovale. Moon and coworkers⁴⁷ reported 30 patients with a history of DCS who were studied with echocardiography for identification of a PFO. Sixty-one percent of 18 patients with serious DCS had shunting, whereas a 25% prevalence was seen in normal volunteers. Wilmschurst and associates⁴⁸ identified a single patient with paradoxical gas embolism through an atrial septal defect and suggested that the atrial septal defect augmented symptoms of DCS. Moon and coworkers⁴⁹ evaluated 90 divers with previous DCS who were studied using echocardiography to detect right-to-left shunting through a PFO. Fifty-nine of 90 had experienced serious decompression symptoms, whereas 31 had experienced pain only or mild symptoms.

In the presence of a PFO, cerebral gas embolism can be caused by venous bubbles transiting a PFO.⁵⁰ Germonpré and associates⁵¹ found that divers with cerebral DCS have a high incidence of large PFO compared to control subjects. Billinger and colleagues⁵² demonstrated an increase in magnetic resonance imaging–detected brain objects in divers with a PFO. Honek and colleagues^{52a} demonstrated that a large PFO could increase risk of DCS in divers with exposures that resulted in significant venous gas emboli. The presence of a PFO may be associated with a twofold to fourfold increase in the risk for DCS.⁵³ The high prevalence of PFO in the population and the very low incidence of DCS suggest that a PFO can play only a minor role in the pathophysiology of DCS. There is no current need to close a PFO as a prophylactic measure.⁵⁴

Table 78-3 Frequency of Decompression Sickness (DCS) Symptoms in 100 Cases

Symptom	Percentage of All DCS Symptoms
Skin itch	4
Headache	11
Fatigue/malaise	13

Age. A 10-year study by the U.S. Air Force on flight exposures ranging from 1500 to 30,000 feet shows a threefold increase in susceptibility to altitude DCS in aviators 42 years of age and older compared with those 18 to 21 years of age.⁵⁵ Carturan and colleagues⁵⁶ found a correlation between bubble formation, increased age, and decreased physical condition in sport divers. Klingmann and coworkers⁵⁷ reported an increased incidence of DCS in novice divers compared to more experienced divers. Blatteau and associates⁵⁸ reported that age and depth of dive exposure increased DCS risk.

Relation to Altitude. Exposure to altitudes above 18,000 feet (0.5 ATA) may result in free gas formation in tissues because of supersaturation of inert gases dissolved at atmospheric pressure.⁵⁹ Divers can develop free gas in tissues when going to higher altitude after diving even though they follow established protocols for ascent from depth to the surface. It is common for sport divers to fly in commercial aircraft (about 8000 feet equivalent altitude) shortly after diving.

Clinical Manifestations

Compared to sport and military divers, commercial divers have the highest incidence of DCS. Musculoskeletal DCS (type I) is the most common form. The incidence of DCS is about 1 in 5000 dives for the sport diver.^{60,61}

DCS can mimic a variety of other disorders (Table 78-3). Free gas entering the venous system will cause varying degrees of pulmonary vascular obstruction. A classic syndrome (“chokes”) manifested by chest pain, dyspnea, and cough is described.⁶² DCS is often associated with free gas in the blood and tissue injury that activates an inflammatory process, with damage to vascular endothelium, microvascular occlusion, and focal regions of tissue ischemia.⁶³ A common manifestation of DCS in divers is spinal cord dysfunction, usually at levels below the diaphragm.⁶⁴ Symptoms include paresthesias, muscle weakness, paralysis of the lower extremities, bowel or bladder incontinence, urinary retention, and sexual impotence.⁶⁵ A sudden ascent from deep depth (blowup) can cause a massive DCS syndrome with both cerebral and spinal neurologic symptoms, unconsciousness, hypovolemic shock, pulmonary edema, and a high mortality rate. A rare but important symptom

of serious (type II) DCS is sudden acute neurologic hearing loss and vestibular dysfunction. DCS of this type usually follows deep, prolonged diving exposures and, if untreated, can result in permanent deafness.⁶⁶

The musculoskeletal form of DCS is manifested by pain in the extremities and joints.^{67,68} Symptoms of local joint pain are often confused with pain from injuries, and the diagnosis of DCS may be missed. In some populations a high incidence of osteonecrosis is found in divers who have experienced musculoskeletal DCS in the distant past or who have experienced deep, prolonged exposures in caisson work,⁶⁸ as well as in diving instructors⁶⁹ and workers in commercial diving operations. An erythematous or purpuric skin rash (cutis marmorata) may also be a manifestation of DCS. A systematic method for diagnosing DCS is described by Grover and coworkers.⁷⁰

Diagnostic Testing

Chest radiography can be used to diagnose pneumothorax, pneumomediastinum associated with pulmonary overpressure accidents, and the pulmonary abnormalities associated with aspiration or capillary leakage associated with chokes. Chest or abdomen CT can be used to diagnose pneumothorax, pneumomediastinum, or pneumoperitoneum. In most cases it is not necessary to postpone recompression treatment in order to obtain radiographic studies. If pneumothorax is suspected, a chest radiograph can be helpful in making the decision to insert a chest tube. Neurologic and psychological testing may be useful in determining response to treatment when brain injury is present. Electronystagmography and audiography may be useful in distinguishing inner ear DCS from inner ear barotrauma. Inner ear DCS requires recompression, whereas inner ear barotrauma is managed with bed rest, avoidance of straining, and possibly surgical intervention. The circumstances causing the two syndromes are distinct (see earlier) and are helpful in the differential diagnosis. Central nervous system injury can be diagnosed by magnetic resonance imaging and correlated with clinical findings.^{71,72} Magnetic resonance images of the brain in divers with no history of decompression-related disorders are also found to be abnormal in some studies.⁷³

Treatment

The clinical manifestations of arterial gas embolism and DCS often overlap. The initial treatment of DCS and arterial gas embolism should always be a return to pressure by recompression in a hyperbaric chamber and administration of oxygen at increased ambient pressure.^{74,75} Fluid replacement and antiplatelet agents are also a part of the initial treatment. Once stabilized with pressure and oxygen, the patient must be decompressed slowly to permit the inert gas to be carried away from tissues by the circulatory system and then to be exhaled by the lungs. With early treatment, DCS and air embolism generally have an excellent prognosis for recovery. When treatment is delayed or when the injury is severe, there may be permanent injury to the brain or spinal cord.

Hyperbaric Therapy. Treatment of DCS and arterial gas embolism should be instituted with recompression as soon as possible after the injury.^{75a} A history and physical evaluation, including a neurologic examination and cognitive

assessment, should be obtained before treatment when possible. Therapy is provided in a hyperbaric chamber by a trained medical team. The usual practice is to follow the standard protocols for pressure treatment outlined in the *U.S. Navy Diving Manual*,⁵ which involves a pressure exposure equivalent to a 60-foot depth in seawater (60 fsw) using intermittent oxygen therapy.

Most practitioners use a hyperbaric treatment protocol lasting about 6 hours (see Table 6 in *U.S. Navy Diving Manual*⁵) for treatment of types I and II DCS. Recompression therapy for cutis marmorata resulting from DCS has been recommended by some, but most cases resolve spontaneously. Itching and erythema of the skin may also be noted following hyperbaric chamber exposures, but these skin findings alone do not require recompression therapy.

When a diver ascends from extreme depths with significant missed decompression, the practitioner may choose to use recompression tables that pressurize the diver to a "depth of relief," to use alternate gas mixtures (i.e., helium and oxygen), or to hold the diver for over 24 hours at a single depth to stabilize the medical status (saturation treatment).⁷⁴ For surface-supplied air and scuba divers, the principal treatment gases are oxygen and air. For treatment depths greater than 60 fsw, enriched nitrogen-oxygen (nitrox) or helium-oxygen (heliox) may also be used.

Repeated hyperbaric oxygen treatments can be given, although end points for repetitive therapy are not well defined. Treatments can be administered until no further change of symptoms is found or for a fixed number of exposures (e.g., five). Controlled trials to determine efficacy of repetitive treatments are not available. Treatment of arterial gas embolism follows similar protocols. Recompression to 60 fsw and oxygen therapy are usually successful.⁷⁶ Recompression to 165 fsw depth equivalent (6 ATA) is recommended if symptoms persist after recompression to 60 fsw.⁵

Supplemental Oxygen and Fluids. Early administration of 100% oxygen on the surface is thought to be beneficial for treating both DCS and arterial gas embolism.⁷⁷ Intravenous fluid administration also may be a useful initial treatment. Central nervous system injury may be exacerbated by hyperglycemia, and glucose-containing intravenous solutions should be administered cautiously. Measurements of hematocrit and urine specific gravity are useful to guide fluid replacement therapy.

Emergency Treatment

Because divers may be injured in areas remote from medical care, treatment measures should be instituted during transit to a hyperbaric chamber facility. Emergency treatment should include 100% oxygen by mask, aspirin 325 to 975 mg by mouth, and Ringer lactate (or normal saline) intravenously. One study of oxygen, aspirin, intravenous fluids, and hydrocortisone 1 to 2 g intravenously during transit to a hyperbaric chamber found that two thirds of the cases had a favorable outcome⁷⁸; however, it remains unproven whether emergency treatment alters long-term outcome. A favorable response to urgent care should not prolong transfer to the closest facility capable of providing recompression therapy.

INERT GAS NARCOSIS

Inert gas narcosis (nitrogen narcosis) results from breathing air at depths greater than 100 fsw.⁷⁹ Symptoms include loss of fine motor control and high-order mental skills, inappropriate response to emotional stress, hostility, and unconsciousness. Symptoms increase with increasing depth below 100 feet. At 300 to 400 fsw, unconsciousness may result from the anesthetic effect of nitrogen at this pressure. Fatigue, heavy work, and hypothermia can augment the narcotic effect of nitrogen. Symptoms disappear immediately on ascending to a shallow depth. Often there is amnesia for the events.⁷⁹ Narcotic potential varies among the inert gases (see [Table 78-2](#)).

OXYGEN TOXICITY

Oxygen toxicity in divers primarily affects the central nervous system.⁸⁰ Pulmonary oxygen toxicity is rare in diving but may be of some concern in prolonged hyperbaric oxygen treatments. Acute toxicity to the brain usually results when oxygen partial pressure exceeds 1.4 ATA. Higher partial pressures can be tolerated for brief periods. The affected diver may experience auditory or visual hallucinations and commonly suffers a grand mal seizure. When underwater, a seizure can lead to drowning. For example, a 32% oxygen mixture will expose a diver to 1.4 ATA of oxygen partial pressure at 111 fsw. Divers have been known to develop seizures when using this breathing gas at depths greater than this.

MEDICAL QUALIFICATIONS FOR DIVING

Military divers have the most stringent requirements, whereas recreational divers have the most relaxed requirements. Commercial divers, caisson and tunnel workers, and hyperbaric chamber workers all have unique standards. Disorders that limit cardiovascular or pulmonary function during exercise, physical deconditioning, metabolic disorders that limit exercise capacity, and certain physical handicaps can compromise diving safety.

EXERCISE REQUIREMENTS

Workloads in diving vary based on the type of diving (see previous). A diver swimming underwater at a speed of 1.0 knot consumes about 25 mL of oxygen per kilogram per minute.⁸¹ Safety considerations suggest that divers should tolerate a sustained workload of about 25 mL/kg/min to ensure safety under adverse diving conditions. Divers who do not achieve this level of fitness should avoid exposures that may require high levels of physical exertion.

DISORDERS CAUSING SUDDEN UNCONSCIOUSNESS

Seizure disorders are considered to be a contraindication to diving because a diver sustaining a seizure underwater is at

risk for drowning and may compromise the safety of others who attempt a rescue. A diving candidate with a history of a seizure disorder should be seizure-free without antiseizure medications for 4 years before being considered for diving.⁸² Insulin-dependent diabetes mellitus is considered a contraindication to commercial and military diving because of the risk for hypoglycemia. Special training has allowed safe diving for insulin-dependent sport divers.⁸³

PULMONARY DISORDERS

Asthma has been a subject of controversy in diving because of possible air trapping and pulmonary overinflation during ascent. Increased risk for pulmonary barotrauma has not been supported by clinical observation.⁸⁴ Criteria for safe diving by patients with a history of asthma include evidence that midexpiratory flow is not reduced after exercise by greater than 50%. A more detailed discussion of issues related to asthma and diving has been published.⁸⁵ Clinical and operational experience suggests that patients with a history of spontaneous pneumothorax or those with bullae or cysts may be at risk for a tension pneumothorax during diving. Treatment requires immediate decompression of the pleural space through an intercostal needle or chest tube and may be difficult at remote diving sites.

CARDIAC DISORDERS

Patients with coronary disease may develop angina pectoris, myocardial infarction, or sudden death while diving. The highest incidence of diving-related death from cardiovascular disease in divers is in the age range from 60 to 70 years.⁸⁶ Of 33 cases of sudden death while diving reported by the Divers Alert Network, 31 were attributed to coronary disease, 1 was related to a stroke, and 1 was related to aortic stenosis.⁸⁷ Screening of diving candidates for coronary disease is particularly important in the sport diving community, where candidates at increased risk for coronary disease due to age and chronic illness may present for training.

Diving candidates with atrial septal defects risk paradoxical embolism of gas bubbles that form in the venous circulation during decompression.⁷⁵ The presence of an atrial septal defect is considered to be a contraindication to diving. Compared to an atrial septal defect, a PFO appears to have a minor role in DCS, and prophylactic closure is not advised. A ventricular septal defect does not appear to produce a risk for paradoxical embolization of bubbles. Patients with a right-to-left shunt and arterial hypoxemia will normally have severely limited exercise capacity and should not dive. A detailed treatment of this topic can be found elsewhere.⁸¹

Diving-Induced Arrhythmias

Reflex bradycardia from diving has been described by a number of investigators⁸⁸ and may be related to the response to facial immersion and cooling found in diving mammals⁸⁹ as well as in humans. The autonomic adjustments to apneic diving in marine mammals appear to be an oxygen-conserving reflex, but this effect does not appear to be significant in humans. Drowning has been associated with the familial-inherited long QT syndrome in swimmers,⁹⁰ and the same risk is likely to apply to divers.

DROWNING

Drowning is reported as the leading cause of death in the approximately 100 to 150 scuba fatalities in the United States each year^{91,92}; however, sudden cardiac death or arterial gas embolism may be the precipitating factor or even the cause of death in many of these accidents.^{93,94} Historically the terms *drowning* and *near drowning* have been used to describe victims who either died or survived, respectively. It is simpler and preferable to use the term *drowning* for all individuals who suffer from submersion incidents.⁹⁵

Intentional hyperventilation before breath-hold diving is associated with drowning episodes. Hyperventilation reduces the arterial PCO₂, so the breath-hold breakpoint is prolonged sufficiently for hypoxemia to develop before the individual is forced to breathe. The hypoxemia in turn causes the individual to lose consciousness, and then drown.⁹⁶ This is termed “shallow water blackout.” Atrial and ventricular arrhythmias are known to happen during prolonged breath-holding experiments, but whether these arrhythmias play an important role in drowning incidents needs further study.⁹⁷

Hypothermia leading to drowning has been reported frequently; however, in diving fatalities this is unusual due to the almost universal use of thermal protection by divers. Hypothermia reduces a person’s ability to function until the point of unconsciousness or helplessness is reached.⁹⁸ At that time, for someone at the surface, the head falls into the water, resulting in drowning. Maximum breath-hold times can drop dramatically in cold water, further compromising the ability to survive in rough water when intermittently submerged. In rare circumstances, hypothermia can have a protective effect on the drowning victim (see later). Hypothermia is only one of many conditions that can precipitate drowning by causing unconsciousness. In the case of scuba diving incidents, contamination of the diver’s air supply with carbon monoxide produces rapid unconsciousness, and oxygen-induced seizures (see earlier) have been implicated as the cause of death in divers using oxygen-enriched air as a breathing mixture.

PATHOPHYSIOLOGY

Approximately 10% to 15% of drowning victims may not aspirate fluid during immersion.⁹⁹ To account for the lack of aspiration in these individuals, it has been hypothesized that reflex laryngospasm persists until reflex ventilatory activity ceases. However, review of early “dry” animal studies does not support the dry drowning hypothesis for fatal cases.¹⁰⁰ It is much more likely that these cases actually represent arrhythmic deaths. In these cases, if ventilation can be reestablished before injury secondary to hypoxemia happens, recovery is typically rapid and uneventful.

Unlike the victim without aspiration, the individual who aspirates remains hypoxemic, even after being removed from the fluid medium and after ventilation is reestablished. As a result, the period of hypoxemia is longer, and secondary damage to other organ systems is more likely.^{101,102} The continuing hypoxemia is due to direct lung injury from the aspirated fluid, which creates areas of low ventilation-perfusion ratio. With saltwater aspiration, it is believed that

hyperosmotic fluid causes transudation of fluid into alveoli, and the aspiration of debris (sand, diatoms, algae, etc.) causes a reactive exudate. As a result, alveoli become filled and are not ventilated. In freshwater aspiration, it is believed surfactant is washed out of the lungs, causing areas of focal alveolar collapse, leading to areas of low ventilation-perfusion ratio, and hypoxemia. These abnormalities persist until the lung damage resolves or until surfactant can be regenerated.

Victims often swallow large amounts of fluid during the drowning episode, so further decreases in ventilatory function may result from gastric distention. Vomiting and aspiration of gastric contents may further complicate the drowning episode. Hypoxemia and decreased alveolar ventilation produce a number of consequences. Arterial PCO₂ quickly rises, and pH quickly falls. Metabolic acidosis can be severe because the victim often struggles during the drowning episode. Finally, there may be cardiovascular collapse, resulting in cardiac arrest. If hypoxemia and decreased cardiac output persist long enough, anoxic cerebral damage can ensue.^{103,104} Although electrolyte disturbances are usually not a significant problem in drowning, the exception to this situation appears to be drowning victims in the Dead Sea, where electrolyte concentrations are greater than those in normal seawater.¹⁰³ The remaining specific consequence of drowning is aspiration pneumonia. The pathogens and the clinical picture of pneumonia associated with drowning have been reviewed extensively.¹⁰⁴

Because, in drowning, cardiac arrest is secondary to hypoxemia, it may be delayed by a significant amount of time. If the water in which the victim is immersed is cold enough, if the surface area-to-mass ratio of the victim is large enough, and if the victim swallows enough water, core temperature may decrease significantly; at low core temperatures the oxygen demands may be low enough that victims can occasionally survive even prolonged submersion.¹⁰⁵

CLINICAL PRESENTATION

The clinical presentation of drowning victims is highly variable. The patient who is unconscious and reported to be without vital signs at the site of the accident may be hemodynamically stable and neurologically intact in the emergency department, whereas the victim initially thought to be hemodynamically stable at the scene might deteriorate significantly before arrival at the hospital.

Cardiovascular System

Victims of significant drowning may suffer cardiac arrest and respond to on-scene resuscitative measures. Whether this represents premature cardiopulmonary resuscitation or a response to therapy is not certain. However, it is also not uncommon for a victim to be brought to the emergency department still requiring cardiopulmonary resuscitation. If the patient “responds” to cardiopulmonary resuscitation at the scene of the rescue with a stable rhythm or if the patient never suffers a cardiac arrest, supraventricular tachycardias are commonly seen. If the patient presents with a viable rhythm, it will most likely be supraventricular tachycardia secondary to hypoxemia and acidosis.¹⁰⁶ Patients with underlying cardiac disease may have a

Table 78-4 Average Blood Gas Measurements in Hospitalized Near Drowning Victims Breathing Room Air upon Admission

	pH	Paco ₂ (mm Hg)	PaO ₂ (mm Hg)	Base Excess (mEq)
Freshwater	7.26	38	66	−9
Seawater	7.37	36	56	−5
All	7.30	37	62	−7

primary cardiac arrest that may mimic a drowning episode.⁹³ The spectrum and frequency of cardiac channel defects in swimming-triggered arrhythmia syndromes may be greater than previously suspected.^{106,107} Pathologic diagnoses may be further complicated by terminal aspiration secondary to agonal breathing after cardiac arrest, and thus postmortem analyses that depend upon aspiration may be misleading.^{108,109}

Pulmonary System

Patients with water aspiration may present with few or no respiratory complaints or with severe pulmonary edema due to direct lung injury.¹¹⁰ Patients who have aspirated any significant quantity of water will likely have a widened alveolar-arterial oxygen gradient and anything from mild to severe hypoxemia. Arterial PCO₂ can be low or elevated depending on alveolar ventilation (Table 78-4). Chest radiographs can show patchy opacities, which are most common in the periphery or in the medial basal regions, or frank (noncardiac) pulmonary edema (see Fig. 78-3). The clinical course cannot be predicted with certainty by the radiographic picture of lung injury. Victims with clear-cut pulmonary difficulties may show minimal radiographic abnormalities, and those with minimal clinical injury may have severely abnormal radiographic pictures.

An interesting form of pulmonary edema found in divers was described by Wilmshurst and colleagues¹¹¹ and by Hampson and Dunford.¹¹² This is manifest as severe dyspnea while diving, associated with arterial hypoxemia, lung congestion, and a normal cardiovascular system. The syndrome may be related to negative-pressure pulmonary edema, a phenomenon well described in the anesthesia literature¹¹³; however, there is also evidence that there are multiple cardiovascular effects that may precipitate this syndrome.^{114,115}

Neurologic Status

The neurologic status of patients can also be quite variable. Severe permanent neurologic injury is the most devastating long-term consequence of the victim of a drowning episode.

TREATMENT

Restoration of normal neurologic function, although unusual, has been described even after prolonged drowning-induced cardiac arrest.¹¹⁶ Because cardiac arrest in this setting is invariably due to hypoxemia and acidosis, the first

goal must be to establish a reliable airway and to supply as high an inspired oxygen concentration as possible. Until the results of arterial blood gas determinations are available, 100% oxygen should be provided. Endotracheal intubation is the preferred method for establishing an airway. This approach needs to take into account the possibility of a concomitant unstable neck injury if there is associated trauma¹¹⁷ as well as the risk for the aspiration of gastric contents. However, without signs or a history of trauma, the risk for an unstable cervical spine injury is low.¹¹⁸

Patients with cardiac arrest due to drowning can have a profound metabolic acidosis. The doses of bicarbonate required to reverse such acidosis may be far larger than the doses recommended for patients suffering cardiac arrest from primary heart disease.¹¹⁹ If bicarbonate is to be given, arterial blood gas determinations are necessary to guide dosing. Concurrently a nasogastric tube should be inserted to decompress the stomach, and body temperature readings should be obtained to rule out hypothermia. In the presence of a significantly lowered body temperature, rewarming measures should be instituted. Once an adequate airway has been obtained and spontaneous cardiac activity achieved, an adequate arterial PO₂ must be established to ensure adequate oxygen delivery to the tissues. Occasional patients will have marked decreases in blood pressure and cardiac output. The initial therapy for hypotension of most causes is a trial of fluids, but, for a drowning victim with pulmonary edema, this may not be appropriate. As a result, this group of patients may require invasive hemodynamic monitoring. With knowledge of pulmonary artery wedge pressure and cardiac output, more rational decisions concerning the need for fluids or pressors can then be made. Isolated measurement of the central venous pressure is generally not an accurate method of judging intravascular volume status in the presence of noncardiac pulmonary edema. In the case of immersion pulmonary edema in a diver, the cause of hypoxemia is not water aspiration, and therapy should include diuretics to reduce lung congestion.¹¹²

Positive end-expiratory pressure is extremely effective in reversing the abnormal ventilation-perfusion relationships leading to hypoxemia. Usually only modest amounts of pressure are necessary to achieve adequate oxygenation. Positive end-expiratory pressure apparently does not alter the course of the underlying pulmonary injury but rather allows for adequate oxygenation while the lung is recovering. It also allows this recovery to take place at a level of inspired oxygen that is not in itself toxic to the lung.^{120,121} Usually the pulmonary injury resolves over a period of 48 to 72 hours, and ventilatory support in most circumstances is relatively brief, unless infection develops. Consequently, in patients who are able to tolerate it, nasal continuous or bilevel positive airway pressure may be a reasonable method for short-term ventilatory support. At present there are insufficient data to warrant the use of inverse-ratio ventilation in cases of drowning.¹²² It may be prudent to manage some drowning victims with high-flow oxygen delivery systems for relatively brief periods before resorting to more invasive methods of providing adequate oxygenation. Optimization of oxygen and carbon dioxide levels (as well as serum glucose level) is likely important to help manage concomitant neurologic injury as well.

The use of antibiotics in the drowning victim who aspirates ocean water or swimming pool water is generally necessary only for those individuals who become febrile, develop new pulmonary opacities, or develop purulent secretions.¹²³ Prophylactic antibiotics do not improve mortality or decrease morbidity.¹⁰³ Because most pulmonary infections in the near drowning victim appear to be hospital acquired, prophylactic antibiotics seem only to select for more resistant organisms.¹²⁴ If the victim aspirates heavily contaminated water with a known or suspected organism (as in the case of aspiration in a hot tub), the use of prophylactic antibiotics may be appropriate. A rare complication of drowning is the aspiration of sand or gravel.¹²⁵ Although bronchoscopy for the routine management of the drowning victim is probably not warranted, consideration of this procedure should be made when unexpected difficulties with mechanical ventilation arise.

Routine use of adrenocorticosteroids to treat the lung injury associated with near drowning is unwarranted. Experimental evidence with this form of aspiration, as well as others, strongly suggests that steroids do not improve the long-term outcome or short-term morbidity.¹²⁶ Artificial and animal-derived surfactants,¹²⁷ extracorporeal membrane oxygenation,¹²⁴ cardiopulmonary bypass,¹²⁸ and hypothermia¹²⁹ have also been used to treat the pulmonary injury associated with drowning. Any victim who has more than minimal respiratory symptoms, an abnormal chest radiograph, or abnormal arterial blood gas measurements should be observed, because pulmonary damage may not be clinically manifest for several hours after the incident.¹³⁰ Nearly all patients who will demonstrate significant problems of gas exchange will do so by 4 to 8 hours after the incident; therefore consideration for discharge from the emergency department may be appropriate in people who can be observed in this fashion.¹³¹ Indeed, current evidence suggests many victims can safely be sent home by lifeguards after a water rescue.¹⁰⁴

PROGNOSIS

The prognosis for the drowning victim depends mainly on the duration of immersion, the length of the anoxic period, and the degree of damage secondary to the anoxic episode. Patients who arrive at the hospital neurologically intact have an excellent prognosis and should survive neurologically unimpaired. An apparent (i.e., undocumented) cardiac arrest does not in itself suggest a poor outcome; however, cardiac arrest that persists through the period of initial first aid and transport to the hospital is a poor prognostic sign. The presence of spontaneous respirations on presentation to the emergency department following cardiac arrest in the field is a good prognostic sign.¹³² The duration of immersion correlates with the degree of damage secondary to the anoxic episode and therefore with the outcome. No prognostic test has proven to be a reliable basis for treatment decisions, and predictions concerning outcome cannot be made in the presence of severe hypothermia.

Key Points

- Middle ear barotrauma is the most prevalent diving injury, whereas pulmonary barotrauma, although uncommon, is the most severe form of barotrauma injury due to the risk for accompanying cerebral arterial gas embolism.
- Decompression sickness results when inert gas dissolved in the body at increased pressure forms free gas in blood and tissues upon decompression.
- Clinical manifestations of acute decompression sickness include disorders of the brain and spinal cord, musculoskeletal pain, chest pain, dyspnea, and skin rash seen up to 24 hours following an exposure to increased pressure.
- Treatment of decompression sickness and arterial gas embolism should be instituted with recompression in a hyperbaric chamber as soon as possible after the injury.
- Assessment for fitness for diving includes consideration of the type of diving (recreational, commercial, military) and a number of chronic disorders that can be aggravated by the diving environment. Because of the increased risk of arterial gas embolism, the presence of an atrial septal defect is considered to be a contraindication to diving.
- Although drowning without aspiration is theoretically possible, the majority of drownings are associated with aspiration of water into the lungs and an accompanying hypoxemia.
- Goals of therapy for a drowning victim include reversing hypoxemia with positive-pressure ventilation and oxygen, treating metabolic acidosis, managing accompanying cardiac arrhythmias, and administering antibiotics when indicated.

INTRODUCTION

The pleural space is bounded by two membranes, the visceral pleura covering the lung and the parietal pleura covering the chest wall and diaphragm. Into this space, normal liquid and protein enter from the systemic circulation and are removed by the parietal pleural lymphatics. Pleural pressure is subatmospheric and ensures inflation of the lung. Because the mesothelial boundaries are leaky, excess liquid can move across into this lower-pressure, high-capacitance space and accumulate as a pleural effusion. Thus, pleural effusions are common and of highly diverse etiologies; effusions can arise from the nearby pleural membranes or from more distant thoracic or abdominal organs. Depending on the protein and *lactate dehydrogenase* (LDH)

concentrations of the liquid, these effusions can be categorized initially as exudates or transudates. Exudative pleural effusions meet at least one of the following criteria, whereas transudative effusions meet none (Light's criteria): pleural fluid protein-to-serum protein ratio of more than 0.5, pleural fluid LDH-serum LDH ratio of more than 0.6, and pleural fluid LDH more than two thirds of the upper normal limit for serum. In this chapter, we discuss both the physiology and pathophysiology of liquid movement in the pleural space.

Other chapters cover the anatomy of the pleural membranes (see Chapter 1) and the pleural diseases related to pleural infections (see Chapter 80) and pleural tumors (see Chapter 82). In addition, pneumothorax, chylothorax, hemothorax, and fibrothorax are covered in Chapter 81.

This introductory chapter covers effusions in general with attention to transudates and those exudative effusions not caused by malignancy and infection.

PLEURA: FORM AND FUNCTION

The two pleural membranes meet at the hilar root of the lung. In the sheep, an animal with a pleural anatomy similar to humans, the surface area of the visceral pleura of one lung, including that invaginating into the lung fissures, is similar to that of the parietal pleura of one hemithorax, approximately 1000 cm².¹ The normal pleural space is approximately 18 to 20 μm in width, although it widens at its most dependent areas.¹ It has been shown that the pleural membranes do not touch each other and that the pleural space is a real, not a potential, space¹ (see Fig. 1-30).

It is likely that the primary function of the pleural membranes is to allow extensive movement of the lung relative to the chest wall. If the lung adhered directly to the chest wall, its expansion and deflation would be more limited. Encased in its slippery coat, the lung, although still coupled mechanically to the chest wall, is able to expand across a breadth of several intercostal spaces. Nonetheless, in clinical and experimental studies, pleural symphysis has not been associated with large abnormalities in lung function.^{2,3} The most common findings have been a decrease in volume of the affected lung and, in one study, of the opposite lung as well.⁴ If pleural thickening accompanies pleural symphysis, abnormalities of lung function may result more from fibrothorax than from obliteration of the pleural space alone.

The visceral pleura may also provide mechanical support for the lung: contributing to the shape of the lung, providing a limit to expansion, and contributing to the work of deflation. Because the submesothelial connective tissue is continuous with the connective tissue of the lung parenchyma, the visceral pleura may help to distribute the forces produced by negative inflation pressures evenly over the lung. In this way, overdistention of alveoli at the pleural surface may be avoided, lessening the chance of rupture and pneumothorax.

One recognized function of the pleural space is to provide a route by which edema can escape the lung.⁵ As has been shown in several experimental studies of either hydrostatic or increased-permeability lung edema,^{6,7} the pleural space can function as an additional safety factor protecting against the development of alveolar edema. The formation of transudative effusions in patients with congestive heart failure apparently reflects the movement of edema from the lung to a space where its effects on lung function are relatively small.

EMBRYOLOGY AND ANATOMY

By 3 weeks' gestational age, the pleural, pericardial, and peritoneal spaces begin to form from the mesoderm and, by 9 weeks, the pleural cavity has become separated from both the pericardial and peritoneal spaces.⁸ Various cysts, diverticulae, and defects can result from incomplete partitioning

of the three mesodermal spaces. As the lung develops, the lung buds invaginate into the visceral pleura and henceforth retain a pleural covering.

The pleural membranes are smooth, glistening coverings for the constantly moving lung. Overlying each pleural membrane is a single cell layer of mesothelial cells. These cells can vary in shape from flat to cuboidal or columnar, perhaps on the basis of the degree of stretching of the underlying submesothelial tissue. These cells, the most numerous of the pleural space, may have a variety of functions important to pleural biology.⁹ Mesothelial cells can secrete the macromolecular components of the extracellular matrix and organize them into mature matrix, phagocytose particles, produce fibrinolytic and procoagulant factors, and secrete neutrophil and monocyte chemotactic factors that may be important for inflammatory cell recruitment into the pleural spaces. The mesothelial cells also produce cytokines such as transforming growth factor-β, epidermal growth factor, and platelet-derived growth factor, cytokines that are important in pleural inflammation and fibrosis.

On their surface are microvilli, which are irregularly distributed over the pleural surfaces. Although microvilli presumably exist to increase surface area for metabolic activity, the function of these prominent features is unknown. Mesothelial cells produce hyaluronan but not mucin, express keratin microfilaments, stain negatively with epithelial-specific antibodies (Ber-EP4, B72.3, Leu.M1, and CEA), and stain positively for calretinin and mesothelin—all features that are important for histochemical and immunohistochemical identification of the cells in pleural effusions.^{10,11}

The cells lie on a thin basement membrane overlying a varying region of connective tissue containing mostly collagen and elastin. Although the parietal pleural connective tissue layer is of a consistent thickness, the visceral connective tissue layer varies greatly. In a single individual, the visceral pleura varies from a thinner layer at the cranial region to a thicker layer at the caudal region.¹² Interestingly, among mammalian species, whereas the parietal pleura is constant, the visceral pleura varies greatly (see Fig. 1-31). Analysis of the constituents of the visceral pleura has shown that there is more collagen relative to elastin than is found in the lung parenchyma, a finding consistent with a mechanical role for the pleura.¹³ This connective tissue layer contains blood vessels and lymphatics and joins with the connective tissue of the lung. The submesothelial tissue has been shown to have mechanical strength and to contain various growth factors that can support cell growth, suggesting that mesothelium could function as a repair and regenerative material.¹⁴

BLOOD SUPPLY

The parietal pleura is supplied by intercostal arteries¹⁵ (Fig. 79-1A). In humans and other large mammals, the visceral pleura is exclusively supplied by the bronchial circulation, which drains into pulmonary veins¹² (Fig. 79-1B). The drainage route via pulmonary veins may have contributed to earlier confusion about whether the visceral pleural blood supply was from a systemic (bronchial) or pulmonary circulation. Both pleurae in humans therefore have a systemic circulation, although the visceral pleural bronchial

Figure 79-1 Light micrograph showing the parietal and visceral pleurae of the sheep, an animal with a similar pleural anatomy to that of humans. Both membranes are covered by a single layer of mesothelial cells (M). **A**, The parietal pleura (PP) is the layer of loose connective tissue between the pleural space (PS) and the dense connective tissue of the endothoracic fascia (EF). Within the loose connective tissue are blood microvessels (A) from the intercostal arteries and lymphatic lacunae (L), which open into the pleural space via stomata. **B**, The visceral pleura (VP) lies between the pleural space (PS) and the alveoli (ALV). The blood supply to the visceral pleura is via the bronchial arteries (A), which drain into pulmonary veins. The pleura contains dense bands of elastin and collagen. (Reproduced with permission from Staub NC, Wiener-Kronish JP, Albertine KH: Transport through the pleura: physiology of normal liquid and solute exchange in the pleural space. In Chrétien J, Bignon J, Hirsch A editors: *The pleura in health and disease*. New York, 1985, Marcel Dekker, pp 174–175, courtesy Marcel Dekker, Inc.)

circulation may have a slightly lower perfusion pressure than the parietal pleural intercostal circulation because of its drainage into a lower-pressure venous system.

LYMPHATICS

If one injects carbon particles into the pleural space as a visible marker of lymphatic drainage pathways, one later finds that the black carbon has been taken up into lymphatics on the parietal side, not the visceral side (Fig. 79–2) (see Fig. 1-32C). The visceral pleura has extensive lymphatics, but they do not connect to the pleural space¹² (see Fig. 1-27). Demonstrated in rabbits, sheep, and now in man, the parietal pleural lymphatics connect to the pleural space via stomas, holes of 8 to 10 μ m in diameter that are formed by discontinuities in the mesothelial layer where mesothelium joins to the underlying lymphatic endothelium (see Fig. 1-32A and B).^{16–18} The stomas can accommodate particles as large as erythrocytes. In various experimental studies, these lymphatics have been shown to be the major route of exit of liquid from the pleural space.¹⁹ From the stomas, liquid drains to lacunae, spider-like submesothelial collecting lymphatics, which then drain to infracostal lymphatics, to parasternal and periaortic nodes, to the thoracic duct, and into the systemic venous system. Lymphoid cells have been described lying within aggregates underneath morphologically different mesothelial cells, forming raised structures called *Kampmeier foci* that may have an immune function, as shown for the peritoneal space.⁹

Figure 79-2 Macroscopic photograph of lymphatic lacunae in the parietal pleura over an intercostal space. Colloidal carbon was instilled into the pleural space to label the draining lymphatics. When one looks down on the pleura, the lymphatic lacunae (L) appear as broad cisterns. B, blood vessel. (Original magnification $\times 39$.) NERVE SUPPLY

The parietal pleura contains sensory nerve fibers, supplied by the intercostal and phrenic nerves, and has long been thought to be the major site of pain sensation in the pleura. The costal and peripheral diaphragmatic regions are innervated by the intercostal nerves, and pain from these regions is referred to the adjacent chest wall. The central diaphragmatic region is innervated by the phrenic nerve, and pain from this region is referred to the ipsilateral shoulder. The visceral pleura has more recently been shown to have sensory nerve fibers that may participate in pain or other sensations such as dyspnea.²⁰ In addition, pleural adhesions may contain pain fibers and contribute to post-thoracotomy or postpleurodesis pain.²¹

PHYSIOLOGY OF THE PLEURAL SPACE

NORMAL PLEURAL LIQUID AND PROTEIN TURNOVER

In the past 10 to 20 years, a consensus has developed that normal pleural liquid arises from the systemic pleural vessels in both pleurae, flows across the leaky pleural membranes into the pleural space, and exits the pleural space via the parietal pleural lymphatics^{22,23} (Fig. 79-3). In this way, the pleural space is analogous to other interstitial spaces of the body. There are several lines of evidence for this view.

1. Intrapleural pressure is lower than the interstitial pressure of either of the pleural tissues. This pressure difference constitutes a gradient for liquid movement into but not out of the pleural space.
2. The pleural membranes are leaky to liquid and protein. Whether tested in vitro^{24,25} or in situ,^{26,27} the pleura offers little resistance to liquid or protein movement.
3. Mesothelial cells express various transporters and aquaporins, but these have not been shown to have a role in reabsorption of effusions.^{28,29} Although normal pleural liquid has been reported to be alkaline with a higher bicarbonate than plasma, there is no evidence for mesothelial participation in generating a bicarbonate gradient. If indeed the mesothelial layer is leaky, it is difficult

Figure 79-3 Schema showing normal pleural liquid turnover. The initial microvascular filtrate in the parietal and visceral pleura is partly reabsorbed (dashed arrows). The remaining low-protein interstitial liquid flows across the leaky pleural mesothelial layers into the pleural space. The pleural liquid exits the pleural space via the parietal pleural lymphatic stomata. (Reproduced with permission from Staub, NC, Wiener-Kronish JP, Albertine, KH: Transport through the pleura: Physiology of normal liquid and solute exchange in the pleural space. In Chrétien J, Bignon J, Hirsch A, eds: *The pleura in health and disease*, New York, 1985, Marcel Dekker, p. 182, courtesy Marcel Dekker.)

to explain how mesothelial cells could maintain such a gradient. (The bicarbonate difference could also be explained by a passive distribution of ions across a semi-permeable membrane, a phenomenon called the *Donnan equilibrium*.)

4. The entry of pleural liquid is slow and compatible with known interstitial flow rates. By noninvasive studies of the equilibration of radiolabeled albumin, the entry rate of pleural liquid is approximately 0.01 mL/kg per hour in a sheep, or about 0.5 mL hourly or 12 mL a day in a grown man.³⁰ The half-time of pleural liquid turnover in sheep and rabbits is 6 to 8 hours.^{30,31}
5. The protein concentration of normal pleural liquid is low in sheep³⁰ and probably in humans, which implies sieving of the protein across a high pressure gradient. The protein concentration of sheep pleural liquid (10 g/L, 1 g/dL) and pleural-to-plasma protein concentration ratio (0.15) are similar to those of filtrates from high-pressure systemic vessels. By comparison, a filtrate from low-pressure pulmonary vessels has a higher protein concentration (45 g/L, 4.5 g/dL) and ratio (lymph-to-plasma protein concentration ratio 0.69).³²
6. The majority of liquid exits the pleural space by bulk flow, not by diffusion or active transport. This is evident because the protein concentration of pleural effusions remains constant as the effusion is absorbed, as is expected with bulk flow. If liquid were absorbed by diffusion or active transport, proteins would exit at a slower rate and the protein concentration would progressively increase. In addition, erythrocytes instilled into the pleural space are absorbed intact and in almost the same proportion as the liquid and protein.¹⁹ This indicates that the major route of exit is via holes large enough to accommodate sheep erythrocytes (6 to 8 μ m diameter). The only possible exit is via the parietal pleural stomas (10 to 12 μ m diameter) into the pleural lymphatics. Of note, these lymphatics have a large capacity for

absorption. When artificial effusions were instilled into the pleural space of awake sheep, the exit rate (0.28 mL/kg per hour) was nearly 30 times the baseline exit rate (0.01 mL/kg per hour).¹⁹

PLEURAL PRESSURE

The pleural pressure in humans is approximately -5 cm H₂O at midchest at functional residual capacity and -30 cm H₂O at total lung capacity.³³ If the compliance of the lung decreased, pleural pressures at the same lung volumes would be more negative. In one study of patients undergoing thoracentesis, those with more negative pleural pressures had a smaller improvement in lung volume than those with less negative pressures, presumably reflecting the presence of underlying diseased, noncompliant lung.³⁴

Although the pleural space pressure is subatmospheric, gases do not accumulate there. The sum of all partial pressures of gases in capillary blood is approximately 700 mm Hg, or 60 mm Hg below atmospheric ($P_{H_2O} = 47$, $P_{CO_2} = 46$, $P_{N_2} = 570$, and $P_{O_2} = 40$ mm Hg). The subatmospheric pressure of dissolved gases in capillary blood helps to maintain the pleural space free of gas and facilitates absorption of any gas that does enter the pleural space. Of note, to increase the gradient favoring absorption of gas, one can lower the partial pressure of nitrogen in the blood by having a patient breathe increased concentrations of inspired oxygen. The oxygen displaces alveolar nitrogen, thereby lowering the partial pressure of nitrogen in capillary blood; because of the limited absorption of oxygen due to the plateau of the oxygen-hemoglobin dissociation curve, however, the increase in inspired oxygen does not add greatly to the partial pressure of oxygen in capillary blood.

PATHOPHYSIOLOGY OF THE PLEURAL SPACE

PLEURAL EFFUSIONS

For pleural liquid to accumulate to form an effusion, it is likely that *both* the entry rate of liquid must increase and the exit rate must decrease. If only the entry rate increased, it would require a sustained rate more than 30 times normal to exceed the reserve lymphatic removal capacity; if the exit rate decreased, it would take more than a month at the normal entry rate of 12 mL per day to produce an effusion detectable by chest radiograph.²³ Thus, in the clinical setting, it is most likely that excess pleural liquid accumulates due to changes in *both* entry and exit rates.

Increased entry of liquid may result from increased filtration across systemic or pulmonary capillaries or entry of another liquid (e.g., chyle, cerebrospinal fluid, urine, intravenous fluid from a displaced catheter). Decreased exit of liquid may result from interference with lymphatic function (e.g., obstruction of the parietal pleural stomas, inhibition of lymphatic contractility, infiltration of draining parasternal lymph nodes, or elevation of the systemic venous pressure into which the lymph drains).²³ There are few studies on the rate of removal of liquid in humans; however, decreases in lymphatic clearance have been confirmed in patients with tuberculous and malignant effusions,³⁵ and

in those with the yellow nail syndrome, a disease of lymphatic function.³⁶ In some cases, it is likely that the same disease process acts to increase entry and reduce exit of liquid whereas, in other cases, different disease processes may act cooperatively to produce an effusion.

To determine the origin of effusions, a classic and useful distinction is between transudates and exudates (see “[Separation of Exudates from Transudates](#)” later).³⁷ Transudates form by leakage of liquid across an intact capillary barrier, owing to increases in hydrostatic pressures or decreases in osmotic pressures across that barrier. Transudates generally indicate that the pleural membranes are not themselves diseased. Exudates generally form from leakage of liquid and protein across an altered capillary barrier with increased permeability. The protein ratio, LDH ratio, and absolute pleural LDH concentration constitute Light’s criteria.

Transudates include various low protein liquids that arise from noninjured capillary beds. The majority of transudates and, in fact the majority of all effusions, are caused by congestive heart failure. These transudates have been shown to form mainly from leakage of edema across normal pulmonary capillaries into the pulmonary interstitium; this interstitial edema can then move toward the pleural space and across the leaky visceral pleura into the pleural space.^{6,38} Other transudates, those associated with the nephrotic syndrome or atelectasis, may form because of altered pressures (osmotic or hydrostatic) across the pleural capillaries. Some transudates, usually small, may develop primarily because of an isolated decrease in exit rate.³⁹ Hepatic hydrothorax and effusions from peritoneal dialysis develop when liquid flows from the peritoneal space into the lower pressure pleural space across macroscopic holes in the diaphragm. Finally, other *very* low protein fluids such as urine or cerebrospinal fluid or intravenous liquids may find their way to the pleural space if their normal course is disrupted.

Exudates arise from injured capillary beds, either in the lung, pleura, or adjacent tissues. Most exudates, such as those associated with pneumonia or *pulmonary embolism* (PE), probably form following lung inflammation and injury when a high-protein lung edema leaks into the pleural space. Another large category of exudates arises from pleural injury due to inflammation, infection, or malignancy. Exudates can also form when exudative liquid in the mediastinum (esophageal rupture or chylothorax), retroperitoneum (pancreatic pseudocyst), or peritoneum (ascites with spontaneous bacterial peritonitis or Meig syndrome) finds its way into the lower-pressure pleural space.

As stated, for either transudates or exudates, lymphatic obstruction may contribute to the accumulation of the effusion. Nonetheless, because lymphatic clearance does not alter the pleural fluid protein concentration, the protein concentration gives information about the *formation* of the fluid, not its *removal*.²³

EFFECTS OF PLEURAL EFFUSIONS ON LUNG AND CARDIAC FUNCTION

In the presence of a space-occupying liquid in the pleural space, the lung recoils inward, the chest wall recoils outward, and the diaphragm is depressed inferiorly and is sometimes inverted.⁴⁰ If the lung and chest wall have

normal compliances, the decrease in lung volume accounts for approximately a third of the volume of the pleural effusion, and the increase in the size of the hemithorax accounts for the remaining two thirds. As a result, lung volumes are reduced by less than the pleural effusion volume. If the lung is otherwise normal, there is no evidence that an effusion causes significant hypoxemia, presumably because ventilation and perfusion decrease similarly. In fact, in one study, mild hypoxemia present before thoracentesis worsened significantly *after* thoracentesis,⁴¹ when perfusion presumably was restored while ventilation remained inadequate. In another study using multiple inert gas techniques to quantify V/Q distributions, pleural effusion was associated with a small intrapulmonary perfusion shunt (6.9%) that did not change significantly when measured again 30 minutes after thoracentesis of approximately 700 mL (6.1%).⁴² Draining pleural effusions in patients with refractory hypoxemia on mechanical ventilation may improve oxygenation,⁴³ although there is no consensus on the indications for thoracentesis in this setting.⁴⁴ It appears therefore that the effects of pleural effusion and thoracentesis on oxygenation are variable and may depend on the underlying lung function.

Large pleural effusions may impair cardiac function, most likely by decreasing the distending pressures on the cardiac chambers and cardiac filling. In a study of 27 patients with large effusions occupying more than half the hemithorax, clinical and echocardiographic findings of cardiac tamponade were identified in most patients. These findings, including elevated jugular venous pressure, pulsus paradoxus, right ventricular diastolic collapse, or flow velocity paradoxus, resolved in all patients when studied again 24 hours after thoracentesis of more than 1 L.⁴⁵ Large pleural effusions, especially left-sided effusions, should be considered as potentially reversible causes of cardiac dysfunction.⁴⁶ Thoracentesis of a unilateral effusion (mean value 1.5 L) has also been shown to improve exercise tolerance.⁴⁷

Common symptoms of patients with effusions are pleuritic chest pain, cough, and dyspnea. It appears that the three symptoms are due to different causes. Pleuritic chest pain derives from inflammation of the parietal pleura and possibly the visceral pleura. Occasionally, this symptom is accompanied by an audible or palpable pleural rub, reflecting the movement of abnormal pleural tissues ([Audio 16-11](#)). Cough may be induced by distortion of the lung, in the same way as cough follows lung collapse from a pneumothorax. Dyspnea is most likely caused by the mechanical inefficiency of the respiratory muscles that are stretched by the outward displacement of the chest wall and the downward displacement of the diaphragm.⁴⁰ After the removal of large amounts of pleural liquid, dyspnea is generally relieved promptly, although the reduction in pleural liquid volume is associated with only small increases in lung volume and little improvement, or an actual decrease, in PO_2 . In one study, nine patients underwent removal of more than 1800 mL of pleural liquid and, despite increases in vital capacity of only 300 mL, all patients experienced immediate relief of dyspnea.⁴⁸ Although the vital capacity changed little, patients could generate a more negative pleural pressure at the same lung volume after thoracentesis than before, indicating an improved efficiency of the

respiratory muscles following the return of the chest wall and diaphragm to a more normal position after thoracentesis. Another related explanation is that dyspnea is due to the inversion of the diaphragm caused by the weight of the pleural effusion, and that dyspnea is promptly relieved when thoracentesis allows the restoration of a dome-shaped diaphragm.⁴⁹ It appears that mechanical effects of a pleural effusion account for dyspnea and for the rapid relief of dyspnea after removal of pleural liquid.

APPROACH TO PATIENTS WITH PLEURAL EFFUSION

Physical findings of a pleural effusion include dullness to percussion, decreased breath sounds, egophony at the upper level of the effusion, and decreased tactile fremitus. With large effusions, signs can include asymmetrical chest expansion or even bulging of the intercostal spaces. A systematic review concluded that the most useful physical findings were dullness to percussion and decreased tactile fremitus⁵⁰ (see Chapter 16).

The possibility of a pleural effusion should be considered in any patient with an abnormal chest radiograph. Increased opacity on chest radiography is frequently attributed to a parenchymal process when it actually represents pleural fluid. Free pleural fluid gravitates to the most dependent part of the thoracic cavity, which is the posterior costophrenic sulcus when the patient is upright. Therefore, if the posterior costophrenic angle is blunted or if the posterior part of the diaphragm is not visible on the lateral chest radiograph, bilateral decubitus chest radiographs (see Figs. 18-7 and 18-9) or an ultrasonic examination (see eFig. 18-21) of the pleural space should be obtained to ascertain whether free pleural fluid is present. If the distance between the inside of the thoracic cavity and the outside of the lung is less than 10 mm, the pleural effusion is not likely to be clinically significant and, in any case, will be difficult to obtain by thoracentesis. If the distance is greater than 10 mm, an effort should be made to determine the cause of the pleural effusion.

DIFFERENTIAL DIAGNOSIS OF PLEURAL EFFUSION

Many different diseases may have an accompanying pleural effusion (Table 79-1). The vigor with which various diagnoses are pursued should depend on the likelihood that the person has that particular disease. Table 79-2 shows rough estimates of the annual incidence of the most common causes of pleural effusions. Congestive heart failure and cirrhosis are responsible for almost all transudative pleural effusions. Pneumonia, malignant pleural disease, PE, and gastrointestinal disease account for at least 90% of all exudative pleural effusions.

SEPARATION OF EXUDATES FROM TRANSUDATES

A diagnostic thoracentesis should be performed on nearly every patient with free pleural fluid that measures more

Table 79-1 Differential Diagnoses of Pleural Effusions

TRANSUDATIVE PLEURAL EFFUSIONS	Collagen vascular diseases
Congestive heart failure	Rheumatoid pleuritis
Pericardial disease	Systemic lupus erythematosus
Hepatic hydrothorax	Drug-induced lupus
Nephrotic syndrome	Immunoblastic lymphadenopathy
Peritoneal dialysis	Sjögren syndrome
Urinothorax	Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)
Myxedema	Granulomatosis with polyangiitis (Wegener)
Central venous occlusion	Post-cardiac injury syndrome
Subarachnoid-pleural fistula	Post-coronary artery bypass surgery
Veno-occlusive disease	Fontan procedure
Bone marrow transplantation	Asbestos exposure
iatrogenic	Sarcoidosis
	Uremia
EXUDATIVE PLEURAL EFFUSIONS	Meigs syndrome
Neoplastic diseases (see Chapter 82)	Ovarian hyperstimulation syndrome
Metastatic disease	Yellow nail syndrome
Mesothelioma	Drug-induced pleural disease
Primary effusion lymphoma	Nitrofurantoin
Pyothorax-associated lymphoma	Dantrolene
Infectious diseases (see Chapter 80)	Methysergide
Pyogenic bacterial infections	Bromocriptine
Tuberculosis	Procarbazine
Actinomycosis and nocardiosis	Amiodarone
Fungal infections	Dasatinib
Viral infections	Radiation therapy
Parasitic infections	Electric burns
Pulmonary embolism	Iatrogenic injury
Gastrointestinal disease	Hemothorax (see Chapter 81)
Esophageal perforation	Chylothorax (see Chapter 81)
Pancreatic disease	
Intra-abdominal abscesses	
Diaphragmatic hernia	
Postabdominal surgery	

Table 79-2 Approximate Annual Incidence of Various Types of Pleural Effusions in the United States

Type of Effusion	Incidence
Congestive heart failure	500,000
Pneumonia (bacterial)	300,000
Malignant disease	200,000
Lung	60,000
Breast	50,000
Lymphoma	40,000
Other	50,000
Pulmonary embolism	150,000
Viral disease	100,000
Post-coronary artery bypass surgery	60,000
Cirrhosis with ascites	50,000
Gastrointestinal disease	25,000
Collagen vascular disease	6000
Tuberculosis	2500
Asbestos exposure	2000
Mesothelioma	1500

than 10 mm on the decubitus radiograph, ultrasound, or chest *computed tomography* (CT) scan. If the patient has obvious congestive heart failure, consideration can be given to postponing the thoracentesis until the heart failure is treated. However, if the patient is febrile or has pleuritic chest pain or if the effusions are not of comparable size on both sides, thoracentesis should be performed without delay.

Thoracentesis is a safe procedure when performed by an experienced operator. Because of the small-bore needle required, it can be safely performed in patients with coagulopathies and thrombocytopenia⁵¹ and in patients on positive mechanical ventilation.⁵² Descriptions of technique emphasize proper positioning of the patient, identification of the area of decreased tactile fremitus that is a sensitive physical finding for the level of the effusion, and adequate local anesthesia of parietal pleura and the skin. The needle should run over the top of the rib to avoid the neurovascular bundle that travels in each intercostal space. Of note, this bundle travels in the middle of the intercostal space from the spine for approximately 5 to 6 inches (13 cm) before taking its safer position beneath the upper rib (eFig. 79-1; also see eFig. 19-1E).⁵² Thus, one should avoid thoracentesis medial to the midclavicular line.

Complications from thoracentesis include pneumothorax and hemothorax (see eFig. 19-1). Estimates of each complication from prospective studies are low (2% to 6% for pneumothorax; 1% for hemothorax), with only half of the pneumothoraces requiring chest thoracostomy.⁵³ Pneumothorax is often associated with procedural events such as aspiration of air, multiple needle passes, and development of new symptoms. The risk for pneumothorax appears to be higher in patients with prior radiotherapy to the chest, multiple prior thoracenteses, or the use of vacuum bottles. In an uncomplicated thoracentesis that is well tolerated by the patient, there appears to be no value for routine chest radiography postprocedure. In addition, routine post-thoracentesis radiographs rarely show new findings.⁵³ Thoracentesis may be safer when guided by ultrasound, although, given the safety of the procedure in uncomplicated cases and the cost or inaccessibility of ultrasound, ultrasound can be selected for higher-risk procedures. For example, it would be appropriate to use ultrasound guidance for thoracentesis on small or multiloculated effusions, in patients with poor lung function or bullous lung disease, and in patients on positive pressure ventilation^{52,54} (see Chapter 20).

The first question that should be answered with the diagnostic thoracentesis is whether the patient has a transudative or an exudative pleural effusion (see “Pleural Effusions” earlier). The identification of transudates or exudates is made by analysis of the levels of protein and *lactate dehydrogenase* (LDH) in the pleural fluid and the serum. Exudative pleural effusions meet at least one of the following criteria, whereas transudative pleural effusions meet none³⁷: (1) pleural fluid protein/serum protein greater than 0.50; (2) pleural fluid LDH/serum LDH greater than 0.60; and (3) pleural fluid LDH greater than two thirds of the upper normal limit for serum. If none of these criteria is met, the patient has a transudative pleural effusion and the pleural surfaces can be ignored while the congestive heart failure, cirrhosis, or nephrosis is treated. In the rare cases

where malignancy has been associated with a transudate, extrapleural effects of the tumor or other causes such as concurrent congestive heart failure are the most likely cause as evidenced by the rarity of a positive cytology in those effusions.^{23,55}

These criteria may misidentify a transudative effusion as an exudative effusion in up to 25% of cases. If a patient appears to have a transudative effusion clinically, additional tests can be assessed to verify its transudative etiology. If the difference between the protein concentration of serum and pleural exceeds 3.1 g/dL or if the difference between the albumin concentration of serum and pleural exceeds 1.2 g/dL, the patient in all probability has a transudative effusion.⁵⁶ If pleural concentrations of *N-terminal probrain natriuretic peptide* (NT-BNP) are elevated (>1300 pg/mL), the patient likely has a transudate from a cardiac cause.⁵⁷

Most studies dichotomize pleural effusions into transudates or exudates on the basis of a single cutoff point. An alternative approach recommended by Heffner and coworkers⁵⁸ is to use likelihood ratios for identifying whether a pleural fluid is a transudate or an exudate. The idea behind this approach is that the higher a value (e.g., the pleural fluid LDH), the more likely the effusion is to be an exudate, and the lower the value, the less likely the effusion is to be an exudate. When these likelihood ratios are used in conjunction with pretest probabilities using Bayes theorem, posttest probabilities can be derived. The difficulty in using this approach is that estimates of pretest probabilities vary significantly from physician to physician. Moreover, most physicians do not understand the mathematics involved. Nonetheless, this approach does emphasize that it is important to take into consideration the absolute value of the measurements. Very high or very low measurements are almost always indicative of exudates and transudates, respectively, while values near the cutoff levels can be associated with either transudates or exudates and can be considered *indeterminate*.

When dealing with a patient who has a high likelihood of having a transudative pleural effusion, the most cost-effective use of the laboratory is to order only protein and LDH levels on the pleural fluid and obtain other laboratory tests only if the fluid turns out to be an exudate. In one study, of 320 pleural fluid specimens submitted for analysis, 83 were found to be transudative.⁵⁹ For these 83 effusions, 725 additional laboratory tests had been ordered, increasing both cost and the incidence of false-positive tests (7/9). If one suspects initially that the patient has an exudate or if the fluid turns out to be an exudate, specimens can be sent for cytology, amylase, glucose, cell count and differential, and cultures.

DIFFERENTIATING EXUDATIVE PLEURAL EFFUSIONS

Once it has been determined that the patient has an exudative pleural effusion, one should attempt to determine which of the diseases listed in Table 79-1 is responsible for the effusion, remembering that pneumonia, malignancy, and PE account for the great majority of all exudative pleural effusions. In all patients with undiagnosed exudative pleural effusions, the appearance of the fluid should be noted and the pleural fluid protein and LDH levels (if not already

obtained), glucose level, differential cell count, and microbiologic and cytologic studies should be obtained.⁶⁰ In selected patients, other tests on the pleural fluid, such as pH, amylase level, antinuclear antibody level, rheumatoid factor level, *adenosine deaminase* (ADA), lipid analysis, and so forth, may be of value. It is certainly not cost effective, however, to obtain all these tests routinely on patients with undiagnosed exudative pleural effusions.

Appearance of Pleural Fluid

The gross appearance of the pleural fluid should always be described and its odor noted. If the pleural fluid smells putrid, the patient has a bacterial infection (probably anaerobic) of the pleural space. If the fluid smells like urine, the patient probably has a urinorhorrax. If the pleural fluid is bloody, a pleural fluid hematocrit should be obtained. If the pleural fluid hematocrit is greater than 50% that of the peripheral blood, the patient has a hemothorax and the physician should strongly consider inserting chest tubes to monitor the rate of bleeding. If the pleural fluid hematocrit is less than 1%, the blood in the pleural fluid has no clinical significance. If the pleural fluid hematocrit is between 1% and 50%, the patient most likely has malignant pleural disease, a PE, or a traumatically induced pleural effusion.⁶¹

If the pleural fluid is turbid, milky, or bloody, the fluid should be centrifuged and the supernatant examined. If the pleural fluid is turbid when originally obtained and the turbidity clears with centrifugation, the turbidity is due to cells or debris in the pleural fluid; if the turbidity persists after centrifugation, the patient probably has a chylothorax (see Fig. 81-8, eFig. 81-8, Video 81-1) or a pseudochylothorax (eFig. 79-2A). These two entities can be differentiated by the patient's history, examination of the sediment for cholesterol crystals (see eFig. 79-2B), and lipid analysis of the supernatant. With chylothorax, the disease process is acute, the pleural surfaces are not thickened, there are no cholesterol crystals present, and the pleural fluid triglyceride level is usually above 110 mg/dL (1.24 mmol/L). With pseudochylothorax, the disease process is usually chronic, the pleural surfaces are usually thickened, there may be cholesterol crystals, and the pleural fluid triglyceride level is usually not elevated. (For further discussion of chylothorax and pseudochylothorax, see Chapter 81.)

Pleural Fluid Protein

The pleural fluid protein level tends to be elevated to a comparable degree with all exudative pleural effusions and is therefore not generally useful in the differential diagnosis of an exudative pleural effusion. However, if the protein level is above 5.0 g/dL, the likelihood of the diagnosis of tuberculous pleurisy is increased. If the pleural fluid protein level is very low (<0.5 g/dL), the patient probably has a urinorhorrax, an effusion secondary to peritoneal dialysis, a leak of cerebrospinal fluid into the pleural space, or an effusion secondary to the misplacement of a central intravascular line.

Pleural Fluid Lactate Dehydrogenase

Whereas pleural liquid protein and LDH arise from filtration from serum and thus serve as indicators of vascular permeability, LDH, as an intracellular enzyme, also may indicate

the degree of cell turnover within the pleural space. Nonetheless, the pleural fluid LDH level is increased to a comparable degree in patients with all categories of exudative pleural effusions and therefore is of no utility in the differential diagnosis of exudative pleural effusion.³⁷ Likewise, the pleural fluid LDH isoenzymes are of limited use in the differential diagnosis of exudative pleural effusions. However, pleural fluid LDH concentration should be measured every time a diagnostic thoracentesis is performed, because the level of LDH in the pleural fluid reflects the degree of inflammation in the pleural space. If the pleural fluid LDH concentration increases with serial thoracentesis, the degree of inflammation in the pleural space is worsening and the physician should be more aggressive in pursuing the diagnosis. Alternatively, if the pleural fluid LDH level decreases with serial thoracentesis, the pleural disease is resolving and observation of the patient is indicated.⁶² When an effusion meets exudative criteria on the basis of LDH but not protein, the effusion is usually malignant or parapneumonic.³⁷

Pleural Fluid Glucose

A low glucose concentration probably indicates the coexistence of two abnormalities: a thickened, infiltrated pleura leading to an impaired diffusion of glucose into the pleural space plus increased metabolic activity leading to increased glucose utilization within the pleural space. The glucose level should be measured in all undiagnosed exudative pleural effusions because the demonstration of a reduced pleural fluid glucose level (<60 mg/dL, 3.3 mmol/L) narrows the diagnostic possibilities to seven: parapneumonic effusion, malignant effusion, tuberculous effusion, rheumatoid effusion, hemothorax, paragonimiasis, or *eosinophilic granulomatosis with polyangiitis* (EGPA, Churg-Strauss).⁶² If a patient with a parapneumonic effusion has a pleural fluid glucose level below 40 mg/dL (2.2 mmol/L), tube thoracostomy should be considered. Many patients with rheumatoid pleural effusions have a pleural fluid glucose level below 30 mg/dL (1.7 mmol/L).⁶³ In contrast, most patients with pleural effusion secondary to *systemic lupus erythematosus* (SLE) will have a pleural fluid glucose level above 80 mg/dL (4.4 mmol/L).⁶⁴ Patients with malignant pleural disease and a low pleural fluid glucose level usually have a positive pleural fluid cytology. In addition, their prognosis is poor, with a mean survival of less than 2 months.^{65,66}

Pleural Fluid White Cell Count and Differential

Pleural liquid that is submitted for white cell count and differential should be sent in a tube with an anticoagulant to prevent the cells from clumping.⁶⁷ In the normal pleural space, the cell count has been reported to be 1700 cells/ μ L.⁶⁸ In effusions, the cell count has limited diagnostic value. A pleural fluid white blood cell count of 1000/ μ L roughly separates transudative from exudative pleural effusion, whereas a pleural fluid white blood cell count above 10,000/ μ L is most common with empyemas and parapneumonic effusions but is also seen with pancreatitis, PE, and collagen vascular diseases and, occasionally, with malignancy and tuberculosis.⁶¹

The differential cell count on the pleural fluid is much more useful than the white cell count itself. The normal

pleural space contains predominantly macrophages (75%) followed by lymphocytes (23%).⁶⁸ A change in differential from this normal distribution provides a clue to the underlying disease process. For the pleural fluid differential cell count, the cells should be partitioned into the following categories: polymorphonuclear leukocytes, eosinophils, small lymphocytes, mesothelial cells, and other mononuclear cells. Pleural effusions due to an acute disease process such as pneumonia, PE, pancreatitis, intra-abdominal abscess, or early tuberculosis contain predominantly polymorphonuclear leukocytes. Pleural effusions due to a chronic disease process contain predominantly mononuclear cells.

Pleural fluid eosinophilia (10% or more eosinophils by differential count) is most commonly due to air or blood in the pleural space. *Interleukin-5* (IL-5) appears to be an important factor because the number and percentage of eosinophils in the pleural space are closely correlated with the pleural liquid IL-5 levels.⁶⁹ Occasionally, no pleural fluid eosinophils are found in the initial thoracentesis, but many eosinophils are seen in a subsequent thoracentesis most likely due to entry of air or blood caused by the initial thoracentesis.⁷⁰ With traumatic hemothorax, pleural fluid eosinophilia does not appear until the second week. The eosinophilia appears to be due to production of IL-5 by CD4⁺ T cells within the pleural space⁷¹ and has been associated with a type 2 innate immune response following a pneumothorax.⁷² At times, the pleural fluid eosinophilia associated with a hemothorax can lead to eosinophilia in the peripheral blood.⁷³ The bloody pleural effusion complicating PE frequently contains many eosinophils.⁷⁴ With pneumothorax, pleural eosinophilia appears within 3 days of the pneumothorax and reaches a peak after 6 days.⁷⁵

After excluding air or blood as the underlying cause, the etiologies of 392 cases of eosinophilic pleural effusions have been reported as follows: idiopathic 40%, malignancy 17%, parapneumonic 13%, tuberculosis 6%, PE 4%, transudates 8%, and other 13%.⁷⁶ If the etiology of the eosinophilia is not evident, several unusual diagnoses should be considered. Benign asbestos pleural effusions are frequently eosinophilic. In one series, 15 of 29 patients (52%) with benign asbestos pleural effusions had pleural fluid eosinophilia.⁷⁰ Patients with pleural effusions secondary to drug reactions (nitrofurantoin or dantrolene) typically have pleural fluid eosinophilia.⁶² The pleural fluid of patients with pleural paragonimiasis is typically eosinophilic with low glucose, low pH, and high LDH level.⁷⁷ EGPA is the only other disease that produces this constellation of pleural fluid findings.⁷⁸

Mesothelial cells line the pleural cavities. It is unusual to find mesothelial cells in effusions due to tuberculosis. However, the absence of mesothelial cells is also common with other conditions in which the pleura becomes coated with fibrin, such as a complicated parapneumonic effusion.

Lymphocytic pleural effusions by definition contain more than 50% small lymphocytes. Most lymphocytic pleural effusions are due to malignancy or tuberculosis. Ninety of 96 exudative pleural effusions (94%) in two series with more than 50% small lymphocytes were due to tuberculosis or malignant disease.^{61,79} Because these two diseases can be diagnosed with needle biopsy of the pleura, the presence of

pleural fluid lymphocytosis should alert the physician to consider needle biopsy of the pleura for diagnosis. In general, separation of pleural lymphocytes into T and B lymphocytes has not been useful diagnostically because most lymphocytic effusions contain a predominance of T cells (CD4⁺) whether the diagnosis is malignancy or tuberculosis.⁸⁰ Such partitioning can be useful diagnostically, however, when a diagnosis of chronic lymphocytic leukemia or lymphoma is suspected. With these diseases the pleural lymphocytes are usually of B-cell origin.⁸¹

Pleural Fluid Cytology

A pleural fluid specimen from every patient with an undiagnosed exudative pleural effusion should be sent for cytopathologic studies. The first pleural fluid cytologic study is positive for malignant cells in up to 60% of the effusions caused by pleural malignancy.⁶¹ If three separate specimens are submitted, up to 90% with pleural malignancy have positive cytopathology. The percentage of cases in which cytologic study of the pleural fluid establishes the diagnosis of a malignant pleural effusion ranges from 40% to 87%.^{61,82,83} The frequency of positive pleural fluid cytologic tests is dependent on the tumor type. For example, less than 25% of patients with Hodgkin disease have positive cytology,⁸⁴ whereas most patients with adenocarcinomas have positive cytology.⁸³ The percentage of positive diagnoses is higher if both cell blocks and smears are prepared by standard protocols and examined by an experienced cytologist.⁸⁵ Each additional sample may increase diagnostic yield in part by providing a higher percentage of fresher cells as older degenerated cells are largely removed by the earlier thoracenteses. During thoracoscopy, pleural lavage has been found to increase the diagnostic yield, perhaps by harvesting more fresh cells for analysis.⁸⁶ The percentage of positive diagnoses is obviously dependent on the skill and experience of the cytologist. Immunohistochemical stains of malignant cells are used to confirm a diagnosis and to specify tumor type, with many new markers available and being used in panels for optimal diagnostic efficacy.^{11,85,87} Cytology can provide enough DNA to assess mutational analysis for *epidermal growth factor receptor* (EGFR) activating mutations when extremely sensitive techniques including next-generation sequencing are used.^{88,89}

Other Diagnostic Tests for Malignancy

Cytology may be nondiagnostic either because of a problem of specificity (e.g., the malignant cells cannot be differentiated from reactive mesothelial cells and “atypical” benign cells) or because of a problem of sensitivity (e.g., the malignant cells are rare). Several assays are being evaluated for their ability to increase the specificity of cytology for diagnosis of malignancy.⁹⁰ *Fluorescent in situ hybridization* (FISH) with chromosome-specific probes can confirm abnormal numbers of specific chromosomes (aneuploidy), thereby confirming that abnormal cells are indeed malignant.⁹¹ Early findings of malignancy including DNA methylation can be detected by methylation-specific *polymerase chain reaction* (PCR)⁹² and gene expression patterns can help distinguish mesothelioma and adenocarcinoma.⁹³ EGFR mutations can predict response to EGFR tyrosine kinase inhibitors. On the other hand, biomarkers have generally been disappointing due to nonspecificity. However, pleural

fluid mesothelin measurements hold promise for the diagnosis of mesothelioma; pleural mesothelin is more accurate than serum for mesothelioma, and a low value can be useful in excluding the diagnosis.^{94,95} However, routine use of mesothelin is not useful⁹⁵ (see Chapter 82).

Culture and Bacteriologic Stains

Pleural fluid from patients with undiagnosed exudative pleural effusions should be cultured for bacteria (both aerobically and anaerobically), mycobacteria, and fungi. Gram stain should also be obtained. In the case of a probable complicated parapneumonic effusion with an initial negative Gram stain, the sediment of the pleural fluid should be stained because the bacteria will be precipitated in the sediment along with the white blood cells and debris. The yield of bacterial culture can be increased by using blood culture bottle cultures in addition to standard cultures; in 62 patients with pleural infection, the added inoculation of a set of aerobic and anaerobic blood culture bottles increased the identification of pathogens from 38% to 59%.⁹⁶

One potentially useful adjunct is molecular detection of bacterial antigens or DNA. This may be especially useful in children for whom the yield from culture is often poor, presumably due to antibiotics given before the thoracentesis.⁹⁷ Such molecular tests can be rapid and more accurate. Antigen-based assays have shown promise in diagnosing empyema caused by *Streptococcus pneumoniae*^{98,99} and *Streptococcus pyogenes*.⁹⁷ Amplification and sequencing of bacterial 16S ribosomal RNA have identified bacteria in pleural empyema, showing in one study of adults that the bacteriology of pleural infections differed from that of pneumonia.¹⁰⁰ It is likely that use of species-specific PCR will become a more standard molecular test for a panel of organisms; it improves detection when compared with 16S PCR and has the potential to make specific diagnoses, although false-positive results are a potential limitation.¹⁰¹

OTHER DIAGNOSTIC TESTS FOR PLEURAL FLUID

Pleural Fluid pH and Pco₂

The pleural fluid pH can be reduced to less than 7.20 with 10 different conditions: (1) complicated parapneumonic effusion, (2) esophageal rupture, (3) rheumatoid pleuritis, (4) tuberculous pleuritis, (5) malignant pleural disease, (6) hemothorax, (7) systemic acidosis, (8) paragonimiasis, (9) lupus pleuritis, or (10) urinothorax.⁶² The decreased pleural fluid pH appears to result from lactic acid and carbon dioxide accumulation in the pleural fluid.¹⁰² The pleural fluid pH is most useful in determining whether chest tubes should be inserted in patients with parapneumonic effusions.¹⁰³ A fall in the pleural fluid pH appears to be a sensitive indicator that the patient has a highly inflammatory parapneumonic pleural effusion that will require drainage.

The routine measurement of pleural fluid pH is recommended only in patients with parapneumonic effusions. In general, pleural fluids with a low pH also have a low glucose¹⁰²; thus, pleural fluid glucose can be used as an alternative to the pH measurement. When the pleural fluid pH is used as a diagnostic test, it must be measured with the same care as arterial pH. The fluid should be collected

anaerobically in a heparinized syringe and placed on ice. If the sample is left open to air, a spuriously high pH value can be obtained because of the rapid loss of carbon dioxide. The pH must be measured with a blood gas machine; a pH meter or indicator paper is not sufficiently accurate.¹⁰⁴ Pleural fluid pH, but not glucose, may be significantly altered by residual air or lidocaine in the syringe.¹⁰⁵ In a 2012 study, 40% of pulmonologists did not appreciate that blood gas analysis was the only accurate method to measure pleural fluid pH and nearly 40% of pulmonologists incorrectly believed their laboratory was using blood gas analysis.¹⁰⁶ The pleural fluid glucose may be a preferable test when the accuracy of pH measurements cannot be assured.

Pleural Fluid Amylase

The pleural fluid amylase is elevated in patients with pleural effusions secondary to esophageal perforation, pancreatic disease, or malignant disease. However, because such a small percentage of effusions are due to esophageal perforation or pancreatic disease, the routine measurement of pleural fluid amylase is not indicated.¹⁰⁷ In the case of esophageal rupture, the origin of the amylase is the salivary glands.¹⁰⁸ In animal models of esophageal rupture, the pleural fluid amylase concentration is elevated within 2 hours of esophageal rupture.¹⁰⁹ In effusions due to pancreaticopleural fistulas, the amylase concentration is extremely high (>4000 IU/mL), reflective of the concentrations in pancreatic secretions.¹¹⁰ In approximately 10% of malignant effusions, the pleural fluid amylase level is mildly elevated. The site of the primary tumor in such patients is usually not the pancreas.¹¹¹ Malignancy can be differentiated from pancreatic disease with amylase isoenzymes because the amylase with malignant effusions is primarily of the salivary type.¹¹² Because lipase originates only from the pancreas, finding lipase in the pleural effusion should help identify the source as the pancreas.

Tests for Collagen Vascular Diseases

About 5% of patients with rheumatoid arthritis¹¹³ and 50% of patients with SLE¹¹⁴ have a pleural effusion sometime during the course of their disease. At times, the effusions may be the first manifestation of the disease; therefore, these diagnostic possibilities should be considered in patients with undiagnosed exudative pleural effusion.

Measurement of the *antinuclear antibody* (ANA) titer is the best screening test for lupus pleuritis, although it is now evident that a positive pleural fluid ANA is not specific for the diagnosis. Although all patients with lupus pleuritis have a positive pleural liquid ANA (>1:40), the finding of a positive ANA has been found in between 11% and 27% of all other effusions.¹¹⁵ Neither the titer of ANA, ratio of pleural-to-plasma ANA, or the pattern of staining has been found to increase the specificity for SLE.¹¹⁶ In fact, a positive pleural fluid ANA in patients without SLE may be associated with malignancy.¹¹⁶ In patients with SLE, the lack of ANA in pleural liquid may have a high negative predictive value; in patients with SLE and a pleural effusion of uncertain etiology, a lack of ANA (dsDNA, *extractable nuclear antigens* [ENA]) in the pleural fluid argues against the diagnosis of lupus pleuritis.¹¹⁷

When a rheumatoid pleural effusion is suspected, the clinical picture usually establishes the diagnosis. If any

question exists, the level of rheumatoid factor in the pleural fluid should be measured. Only patients with rheumatoid pleuritis have a pleural fluid rheumatoid factor titer equal to or greater than 1 : 320 and equal to or greater than the serum titer.¹¹⁸

Adenosine Deaminase

ADA, a product of activated lymphocytes, catalyzes the conversion of adenosine to inosine and is important for normal immune function. The pleural fluid ADA levels are elevated in almost all patients with tuberculous pleuritis but not with other conditions even when associated with lymphocytic effusions.¹¹⁹ Despite earlier concerns about false-negative values in HIV-positive patients, ADA remains a sensitive marker for tuberculous pleurisy in patients with HIV.¹²⁰ ADA levels can be elevated in other conditions and also in neutrophilic effusions; in one study, ADA above the cutoff (35 U/L) was seen in up to 40% of parapneumonic effusions and in half of effusions due to lymphoma.¹²¹ Because it is a highly sensitive test, the ADA can be a useful test to exclude the diagnosis of tuberculosis when the ADA level is low (<40 U/L).¹²²

Interferon Gamma

Interferon gamma, a T-cell lymphokine, may play a critical role in the effective clinical response to *Mycobacterium tuberculosis*. Pleural liquid interferon gamma is elevated almost exclusively in tuberculous effusions.¹²³ Interferon gamma appears to be as useful as ADA; because ADA is less expensive, ADA is generally preferred. Compared with ADA and interferon gamma, the interferon gamma release assays of pleural fluid, however, have not been shown to be of use in the diagnosis or exclusion of active pleural tuberculosis; these tests are not currently recommended for pleural fluid.¹²⁴⁻¹²⁶

Molecular Techniques for Diagnosis of *Mycobacteria tuberculosis*

Four molecular techniques are now available: PCR to detect specific mycobacterial DNA sequences in clinical specimens (pleural liquid or biopsy), nucleic acid probes to identify the organism in culture, restriction fragment length polymorphism to compare strains in epidemiologic studies, and gene-based susceptibility studies to screen for known genes associated with drug resistance.¹²⁷

In theory, PCR tests have great potential for providing a rapid, highly sensitive and specific diagnosis of mycobacterial infection. In practice, PCR amplification of clinical samples has been limited by a low sensitivity,¹²⁸ which may be due to degradation of the target DNA by sample processing or by inhibitors of amplification in clinical fluids. PCR amplification assays show a high specificity and thus, when positive, can help in making the diagnosis; however, because of their low sensitivity, they are not useful in excluding the disease.¹²⁹ Before wide application of PCR assays, considerations will also include its cost and current inability to identify antibiotic resistance of the organism. In the future, molecular techniques for diagnosis of tuberculosis and for other slow-growing microorganisms will likely prove increasingly important.

USEFUL RADIOGRAPHIC TESTS IN PATIENTS WITH SUSPECTED PLEURAL DISEASE

The possibility of a pleural effusion should be considered whenever a patient with an abnormal chest radiograph is evaluated. Two main factors influence the distribution of free fluid in the pleural space. First, the fluid collects in the most dependent part of the thoracic cavity because the lung is less dense than the pleural fluid. Second, because of their elastic recoil, the lobes of the lung generally maintain their traditional shape at all stages of collapse.

When the patient is upright, the fluid first accumulates between the inferior surface of the lower lobe and the diaphragm. If there is less than 75 mL of fluid, it may occupy only this position without overflowing into the costophrenic sinuses. When more fluid accumulates, it spills over into the posterior costophrenic angle and obliterates the posterior part of the diaphragm on the lateral projection. The possibility of a pleural effusion should be suspected whenever the posterior part of one or both diaphragms is obscured (see Fig. 18-9). The presence of a clinically significant amount of free pleural fluid can be excluded if both posterior costophrenic angles are clear. Pleural effusions on radiography can be missed in the setting of lower lobe consolidation and, in the setting of pneumonia, consideration should be given to seeking the presence of effusions with additional imaging.¹³⁰

When there are larger amounts of pleural fluid, the lateral costophrenic angle on the posteroanterior radiograph becomes blunted. Collins and associates¹³¹ demonstrated that at least 175 mL of pleural fluid had to be injected into the pleural space of cadavers before the lateral costophrenic angle was blunted. In some of their cases, more than 500 mL of pleural fluid could be present without blunting the lateral costophrenic angle. As more fluid accumulates, the entire outline of the diaphragm on the affected side is lost, and the fluid extends upward around the anterior, lateral, and posterior thoracic walls, producing opacification of the lung base and the typical meniscus shape of the fluid.

The changes just discussed are suggestive rather than diagnostic of the presence of pleural fluid. Lateral decubitus radiographs (see Figs. 18-7 and 18-9) or ultrasonic examination should be obtained in most instances when free pleural fluid is suspected. If the entire hemithorax is opacified, decubitus radiographs are of no use, because there is no air-containing lung in the hemithorax. The basis for the use of the lateral decubitus view is that free fluid gravitates to the most dependent part of the pleural space. When a patient is placed in the lateral recumbent position, the free pleural fluid on the dependent side accumulates between the chest wall and the lung (Fig. 79-4). As little as 5 mL of pleural fluid can be demonstrated with properly exposed decubitus radiographs.¹³² The amount of pleural fluid can be semiquantitated by measuring the distance between the inner border of the chest wall and the outer border of the lung (see Fig. 79-4). As already stated, when this distance is less than 10 mm, the amount of pleural fluid is small and a diagnostic thoracentesis is usually not attempted.

Pleural fluid may become encapsulated by adhesions anywhere between the parietal and the visceral pleurae or

Figure 79-4 Left lateral decubitus chest radiograph demonstrating the presence of free pleural fluid. The amount of pleural fluid can be semiquantified by measuring the distance between the two arrows.

in the interlobar fissures. Pleural fluid loculates most frequently in association with conditions that cause intense pleural inflammation, such as with a complicated parapneumonic effusion or tuberculous pleuritis. When the loculation is situated between the lung and the chest wall, there is a characteristic radiographic picture. The loculation is “D” shaped with the base of the D against the chest wall and the smooth convexity protruding inward toward the lung (see Fig. 18-39). The absence of air bronchograms helps differentiate a loculated pleural effusion from a parenchymal process. A definite diagnosis of loculated pleural effusion is best established by ultrasonography or CT.

Ultrasound

One way to document and locate loculated pleural fluid is with ultrasound. In the presence of pleural fluid, the proximal echoes from the skin, intercostal muscles, and parietal pleura are separated from the distal echoes arising from the visceral pleura and the lung by a central echo-free space. The advantages of ultrasound over CT are the ease and speed with which the examination can be performed, the lack of ionizing radiation, the relatively low cost, and the ability to provide continuous guidance for thoracentesis or pleural biopsy.¹³³

The appropriate site for a thoracentesis can be identified using ultrasound.⁵² If a patient has a moderate or large effusion, the thoracentesis may be performed without ultrasound but large studies have shown a lower incidence of pneumothorax when ultrasound is used.¹³⁴ Ultrasound should definitely be used if no fluid is obtained on an initial attempt or if the effusion is small. When ultrasound is used to identify the site for thoracentesis, it is important to perform the thoracentesis at the time of the ultrasonic examination. If the skin is marked and the patient returned to his or her room, thoracentesis may be unsuccessful because the relationship between the skin and the pleural fluid may have changed. In addition, when the thoracentesis is performed at the time of the ultrasonic examination, there is immediate feedback that is valuable in improving the skill of the ultrasonographer (see Chapter 20).

Computed Tomography

Chest CT is currently the best way to visualize the pleural space.¹³³ Chest CT has its greatest utility in distinguishing parenchymal and pleural abnormalities.¹³⁵ With current protocols involving the rapid injection of intravenous contrast medium, the unaerated perfused lung parenchyma will enhance, whereas the pleural fluid will not.¹³⁶ The use of CT to discriminate transudates from exudates by their attenuation (Hounsfield units) has not been found to be clinically useful due to a great deal of overlap.¹³⁷

Chest CT is quite useful in distinguishing a parenchymal lung abscess located near the chest wall from an empyema with an air-fluid level. The most distinctive features are the margins of the abnormality. With empyema, the cavity walls are of uniform thickness both internally and externally (see eFigs. 80-2, 80-5) and the adjacent lung is usually compressed. The angle of contact with the chest wall may be obtuse (see eFig. 33-7B). In addition, most empyemas have a lenticular shape and demonstrate the “split pleura” sign (Fig. 79-5A see also eFigs. 80-2, 80-5).¹³⁸ With lung abscess, the walls of the cavity are not of uniform thickness and the adjacent lung is not compressed (see eFigs. 33-4, 33-13B and C, 33-21D and E). The angle of contact with the chest wall may be acute (Fig. 79-5B).

In diffuse pleural disease, chest CT is useful in distinguishing malignant from benign causes. Features associated with malignancy include circumferential pleural thickening, pleural nodules (see eFig. 53-5), parietal thickening greater than 1 cm, and mediastinal pleural involvement (see eFig. 53-4 and Video 79-1).¹³⁹ The distinction of metastatic disease from mesothelioma can be difficult, although hilar adenopathy is more common with metastatic disease.¹³³

CT pulmonary angiography (CTPA) has become a first-line imaging test for the evaluation of PE¹⁴⁰ (see Chapters 18 and Chapter 57). The evaluation of a patient with a pleural effusion for PE can begin with a Doppler ultrasound of the lower extremities. If the ultrasound identifies thrombus, the patient can then be treated for thromboembolic disease. If it is negative, the patient may still have a PE. In the past the standard approach was to proceed to lung ventilation-perfusion scanning. However, this has largely been replaced by CTPA. CTPA is highly sensitive and specific for pulmonary emboli in the proximal, segmental pulmonary arteries.¹⁴⁰ In contrast to ventilation-perfusion lung scanning, CTPA can establish alternate diagnoses as well. Where CTPA is not available, lung scanning can be used, perhaps after efforts to improve accuracy by withdrawing as much pleural liquid as possible. A diagnostic scan (normal or high probability) can then be used either to exclude the diagnosis or initiate anticoagulation. If nondiagnostic (e.g., of low or intermediate probability), the scan should be followed by pulmonary angiography.

Magnetic Resonance Imaging

At present, *magnetic resonance imaging* (MRI) of the chest is less satisfactory than ultrasound or CT in identifying the presence of pleural fluid.¹³³ It is possible that with improved MR technology, the characteristics of pleural fluid can be determined noninvasively. Respiratory and cardiac motion

Figure 79-5 Typical CT features of a pleural empyema versus a lung abscess. **A**, Axial CT through the lower thorax in a patient with fever and pleuritic chest pain shows features typical of empyema, including the formation of obtuse angles between the lesion and chest wall (arrowhead), a lenticular shape, a smooth internal surface (arrows), and mass effect on surrounding structures (note leftward shift of the heart and great vessels). Note enhancement of the parietal and visceral pleura, representing the “split-pleura” sign (arrows) and the presence of an air-fluid level, indicating the presence of a broncho-pleural fistula. **B**, Axial CT through the mid thorax in a patient with fever and cough productive of foul-smelling sputum shows features typical of a pulmonary abscess, including the formation of acute angles between the lesion and chest wall (arrowhead); a round shape; a thick, irregular internal surface (arrows); and relatively little mass effect on surrounding structures, despite the large size of the lesion. The lack of mass effect results because pulmonary abscesses tend to destroy adjacent lung more than they displace it. An effusion, found to be an empyema (E), is also present.

is the major limitation in evaluating specific intensity patterns of fluid collections of various compositions. MRI may have current value in delineating malignancy in the pleural space and may be better than chest CT for determining chest wall or diaphragmatic invasion.

Positron Emission Tomography and PET/CT

Positron emission tomography (PET) visualizes tissues that are metabolically active by their concentration of the radioisotope ^{18}F -fluorodeoxyglucose. Because most malignant cells have a higher metabolic rate than nonmalignant cells, PET can help differentiate malignant from benign lesions, stage patients with malignancy, and identify recurrence.¹³³ Introduced in 1998, PET/CT integrates the metabolic information of PET with the detailed anatomic information of CT. Compared with CT or PET alone, PET/CT can allow detection of additional lesions, localize them more accurately, characterize them as highly likely to be malignant, and discriminate malignant from surrounding normal tissue¹⁴¹ (see Chapter 82).

INVASIVE TESTS IN PATIENTS WITH UNDIAGNOSED EXUDATIVE PLEURAL EFFUSIONS

In the patient with an undiagnosed exudative pleural effusion, several invasive tests might be considered, including blind or image-guided needle biopsy of the pleura, bronchoscopy, thoracoscopy or video-assisted thoracic surgery, and open biopsy of the pleura. It is important to remember that no diagnosis is ever established for approximately 20% of all exudative pleural effusions and that many resolve spontaneously, leaving no residua.^{122,142} In patients with undiagnosed exudative pleural effusions, three factors should influence the vigor with which one pursues the diagnosis with invasive tests. First, the symptoms and clinical

course of the patient. If symptoms are minimal or improving with time, a less aggressive approach is indicated. Second, the trend of the pleural fluid LDH level with time. If the pleural fluid LDH increases with serial thoracenteses, a more aggressive approach is indicated. Third, the attitude of the patient. If the patient is anxious about the cause of the pleural effusion, an aggressive approach should be taken. Furthermore, when an undiagnosed exudate resolves without treatment, two diagnoses should still be considered and excluded: PE and tuberculosis.

Needle Biopsy of the Pleura

Small specimens of the parietal pleura can be obtained with needle biopsy, often called *blind* or *closed needle biopsy*. The needles most commonly used for this procedure are the Cope needle and the Abrams needle.⁶² Because needle biopsy of the pleura is useful mainly to establish the diagnosis of malignant or tuberculous pleural effusions, this procedure should be considered when one of these diagnoses is suspected.

In malignant pleural disease, the needle biopsy of the pleura will be positive in 40% to 60% of patients.¹⁴²⁻¹⁴⁴ Overall, the yield from pleural fluid cytology tends to be higher, probably because it samples cells dislodged from the entire pleura, while the needle biopsy can only sample from a localized area. In one series of 281 patients with malignant pleural effusions, the pleural biopsy was positive in 43%, whereas the pleural fluid cytology was positive in 58%.¹⁴² In 7% the pleural biopsy was positive and the pleural fluid cytology negative.¹⁴² In a more recent study of 66 patients, although cytology was more likely to be positive than biopsy (69% vs. 48%), closed pleural biopsy added diagnoses in some cytology-negative patients.¹⁴⁴ A prudent approach to the patient with a suspected malignant pleural effusion is to obtain a pleural biopsy only if the cytology obtained at the time of the initial diagnostic thoracentesis

is nondiagnostic. If the CT shows pleural thickening or nodularity, an image-guided pleural biopsy is an excellent option.¹⁴⁵

Needle biopsy of the pleura has greater utility for the diagnosis of tuberculous pleuritis than of malignancy. The initial biopsy is positive for granulomas in 50% to 80% of patients.¹⁴⁶ The demonstration of granulomas on the pleural biopsy is virtually diagnostic of tuberculous pleuritis; caseous necrosis or acid-fast bacilli need not be demonstrated, although on rare occasions, fungal diseases, sarcoidosis, or rheumatoid pleuritis can produce granulomatous pleuritis. When tuberculous pleuritis is suspected, a portion of the pleural biopsy specimen should be cultured for mycobacteria. In one series of 21 patients with tuberculous pleuritis, either the microscopic examination or the biopsy culture was positive in 20 of the 21 patients (95%)¹⁴⁷; in a more recent series of 113 patients with tuberculous pleural effusion, the sensitivity of closed pleural biopsy (by showing granulomas on pathology or culture) was 92%.¹⁴⁸ If the initial biopsy is nondiagnostic and the patient has tuberculous pleuritis, a second biopsy will be diagnostic 10% to 40% of the time.^{146,149}

The greatest value of needle biopsy for a patient with tuberculosis is in obtaining material for culture of *M. tuberculosis* for the determination of drug susceptibility. Often, the presentation of a patient with a recent purified protein derivative conversion and an exudative pleural effusion with lymphocytosis is classic and unlikely to be due to any diagnosis other than tuberculous pleurisy. The diagnosis can be further supported by measurements, where available, of pleural fluid ADA or interferon gamma. In those cases, treatment for tuberculosis can be offered with confidence without needle biopsy confirmation. However, when the patient may have been exposed to drug-resistant organisms, needle biopsy will increase the likelihood of obtaining organisms for culture and is recommended. Sputum induction can also be useful for culturing the organism, even when only pleural involvement is suspected and the chest radiograph shows no pulmonary involvement; in this setting, sputum induction has been shown to have a yield similar to culture of the pleural biopsy (52% vs. 62%).¹⁵⁰ Medical thoracoscopy has a higher yield than blind needle biopsy for obtaining pleural material for culture. When different approaches were compared in the same 51 patients, thoracoscopy obtained a positive culture of *M. tuberculosis* in 76%, whereas the Abrams needle obtained a culture in 48%.¹⁵¹ If the need for obtaining positive cultures is high, the more invasive diagnostic tests including medical thoracoscopy may be preferred.

The two major complications of needle biopsy of the pleura are pneumothorax and bleeding. Pneumothoraces require a chest tube in only about 1% of pleural biopsies.^{142,152} It is likely that many pneumothoraces develop because of leakage of air through the biopsy needle and do not necessarily indicate puncture of the lung. A hemothorax can result from inadvertent biopsy of an intercostal artery or vein. In one older series, a fatal hemothorax was a complication in 2 of 227 biopsy procedures.¹⁵² The pleural biopsy needle can also be mistakenly inserted into the liver, spleen, or kidney, which can lead to hemorrhage in these organs. However, in general, bleeding complications are rare.

If no diagnosis is obtained after routine laboratory tests including cytology and one needle biopsy of the pleura, what can be said concerning the patient? Poe and coworkers¹⁵² followed 143 such patients for 12 to 72 months, during which time 29 patients were diagnosed with malignant pleural disease and one patient with tuberculous pleuritis. In all 29 cases in which malignancy was eventually diagnosed, the diagnosis of malignant neoplasm was suggested by clinical criteria such as weight loss, constitutional symptoms, or a history of previous cancer. These authors concluded that most patients with undiagnosed exudative pleural effusions in whom the clinical picture does not suggest malignancy are best managed by observation. In those with symptoms suggestive of malignancy, image-guided pleural biopsy or thoracoscopy are probably the procedures of choice.

Image-Guided Pleural Biopsy

In patients with pleural abnormalities consistent with malignancy, CT-guided cutting-needle biopsies may supplant closed pleural biopsy for diagnosis, where image-guided technology is available.¹⁵³ In a randomized study of 50 patients with suspected malignant pleural effusions with negative cytology, those randomized to image-guided biopsy were more likely to be diagnosed (87% sensitivity) than those randomized to blind pleural biopsy (47%).¹⁴⁵ In situations where the effusion is small and there is loculation or pleural thickening without an effusion, CT image-guided pleural biopsy is an excellent choice. PET/CT may increase the yield further by improving interpretation and selection of biopsy targets (see earlier).

Bronchoscopy

Another procedure that should be considered in the patient with an undiagnosed pleural effusion is bronchoscopy (see Chapter 22). If the patient has an associated parenchymal lesion or hemoptysis, fiberoptic bronchoscopy will provide a diagnosis in nearly 75%.¹⁵⁴ On the other hand, if the patient has neither a parenchymal abnormality nor hemoptysis, a diagnosis for the pleural effusion is established less than 10% of the time.¹⁵⁵ At present, chest CT should be performed in all patients with undiagnosed exudative pleural effusions. Bronchoscopy should then be performed only if the CT scan demonstrates parenchymal or obstructing airway abnormalities or if the patient has hemoptysis. At the time of bronchoscopy, special attention is paid to those portions of the lung in which the parenchymal abnormalities were demonstrated.

Thoracoscopy or Video-Assisted Thoracic Surgery

Thoracoscopy is discussed fully in Chapter 24. Thoracoscopy may be useful diagnostically in patients in whom the origin of a pleural effusion remains unclear after routine fluid analysis and needle biopsy of the pleura. In many cases, especially for the evaluation of malignancy, thoracoscopy may supplant needle biopsy because of a greater diagnostic yield and the added ability to provide a pleurodesis. Thoracoscopy can be performed by pulmonologists using local anesthesia and conscious sedation for direct visualization of the pleural surfaces, tissue sampling, and pleurodesis; thoracoscopy performed by thoracic surgeons, generally referred to as *video-assisted thoracic surgery* (VATS),

utilizes general anesthesia and single-lung ventilation by double-lumen intubation and allows greater access to the pleura and lung for surgical procedures.

Which patients with undiagnosed pleural effusions should undergo thoracoscopy? A diagnosis can be established in more than 90% of patients with malignancy including those with mesothelioma.¹⁵⁶ Moreover, talc can be insufflated at the time of the procedure and this will control the effusion in the majority of patients. Nonetheless, there are minor risks of the procedure, a need for post-procedure chest tube(s), and a procedure cost that should be considered. Thoracoscopy is therefore recommended for the patient with an undiagnosed pleural effusion after diagnostic thoracentesis and needle biopsy of the pleura in whom the diagnosis of malignancy is strongly suspected and in whom one wishes to establish this diagnosis.

Open Biopsy of the Pleura

Thoracotomy with direct biopsy of the pleura provides the best visualization of the pleura and the best biopsy specimens. Nowadays, the less invasive thoracoscopy can replace thoracotomy in most instances. The main indication for open pleural biopsy is progressive undiagnosed pleural disease that cannot be approached by or has failed to be diagnosed by thoracoscopy. In the past, for example, the diagnosis of malignant mesothelioma was usually made with open biopsy of the pleura, but now the diagnosis can be established in the majority of the cases with thoracoscopy.

It should be emphasized that open pleural biopsy does not always provide a diagnosis in patients with pleural effusions. Over the 11-year period from 1962 to 1972, 51 patients with pleural effusion at the Mayo Clinic had no diagnosis after an open pleural biopsy.¹⁵⁷ In 31 of these patients (61%), there was no recurrence of the pleural effusion, and no cause ever became apparent. However, 13 of the patients were eventually proved to have malignancy; 6 had lymphoma and 4 had malignant mesothelioma. Thus, observation of patients with undiagnosed pleural effusions is often warranted unless there is compelling reason to pursue the diagnosis of malignancy. Since the time of this study, there have been many improvements in diagnostic tests that may increase the diagnostic yield of invasive procedures and the treatment options available.

TRANSUDATIVE PLEURAL EFFUSIONS

Transudative pleural effusions frequently accompany many common clinical disorders. It is noteworthy that the primary abnormality in most cases of transudative pleural effusions originates in organs other than the pleura or lungs, especially the heart, liver, and kidneys. This association emphasizes the fact that although patients may visit their physicians for respiratory complaints, these symptoms may be caused by extrapulmonary disorders.

CONGESTIVE HEART FAILURE

Congestive heart failure (CHF) is probably the most common cause of pleural effusion.⁶² The incidence of pleural effusion

in patients with CHF is high. In one series of 60 patients with an exacerbation of stable CHF, chest CT scans demonstrated that 50 patients (83%) had a right-sided pleural effusion and 46 patients (77%) had a left-sided effusion. Approximately one third of the effusions had a volume that exceeded 700 mL.¹⁵⁸

Pathophysiology

The pleural fluid that accumulates with CHF is related to the clearance of pulmonary interstitial fluid across a leaky mesothelium into the pleural space.⁵ In studies in which sheep lungs were isolated in situ, volume loading led to an increased transudation across the lung into the pleural space.⁶ The pleural fluid had the same protein concentration as that of the lung lymph and the interstitial edema liquid in the lung. The volume of pleural fluid constituted about 25% of all edema formed in the lung.⁶ In the clinical situation, patients with CHF are much more likely to have a pleural effusion if there is radiologically apparent pulmonary edema.¹⁵⁹

Clinical Manifestations

Patients with pleural effusion resulting from CHF usually have symptoms and signs of heart failure, such as dyspnea on exertion, orthopnea, nocturia, peripheral edema, distended neck veins, crackles, and a cardiac gallop. The chest radiograph almost always reveals cardiomegaly in addition to the pleural effusion.

The pleural effusions seen with CHF tend to be bilateral, with larger effusions on the right (Fig. 79-6A). On CT imaging, interstitial and alveolar edema can often be detected by the presence of thickened septae and patchy opacities (Fig. 79-6B and Video 79-2). Thickened septa represent interstitial edema, as seen in edematous lungs frozen to demonstrate the location of edema; the interstitial edema is continuous with the interlobular septa and the subpleural space, from which the edema has been shown to move across the visceral pleura to the pleural space (Fig. 79-6C).⁶

In an autopsy study of 250 patients with CHF and pleural effusion, 88% of the patients had bilateral pleural effusions, with the mean volume of pleural fluid in the right pleural space (1084 mL) slightly greater than the mean volume of fluid in the left pleural space (913 mL).¹⁶⁰ Moreover, of the 35 patients who did have unilateral pleural effusions, 46% had either PE or pneumonia.¹⁶⁰ Weiss and Spodick¹⁶¹ reported that 73% of 51 patients with CHF had bilateral effusions, 19% had unilateral right-sided effusions, and 9% had unilateral left-sided effusions. In a study of 100 patients with bilateral pleural effusions, CHF was the most common contributor to effusions, but often the causes were multiple; in fact, most of the effusions were exudative and, of these, CHF was the second most common cause.¹⁶²

The reason that effusions are generally larger on the right side may lie in the fact that they originate from the larger lung on the right side.³⁹ In volume-overloaded sheep, the rate of liquid leakage from the right lung was higher than from the left, likely due to the larger volume and surface area of the right lung.⁶ In another study in awake sheep, there was no difference in the rate of absorption of effusions from the right and left pleural spaces,¹⁹ suggesting that differences in formation are the cause of the difference in size.^{19,39}

Figure 79-6 Effusion from congestive heart failure. **A**, Frontal chest radiograph in a patient with pulmonary edema shows cardiomegaly, bilateral pleural effusions (*larger arrows*), and central interstitial thickening, including Kerley A lines (*small arrow*). Note that the right effusion is slightly larger than the left effusion. **B**, Chest CT scan in a patient with pulmonary edema shows interstitial edema with bilateral, basilar centrilobular ground-glass opacity nodules (*arrowhead*) and smooth interlobular septal thickening (*arrows*). Bilateral pleural effusions are also present. **C**, Frozen sheep lung after volume loading showing edema as a continuous band (between *arrows*) from the interlobular septa (S) to beneath the visceral pleura (V), which it can cross to enter the pleural space. Horizontal bar = 1 mm. (**C**, Reproduced with permission from Broadus VC, Wiener-Kronish JP, Staub NC: Clearance of lung edema into the pleural space of volume-loaded anesthetized sheep. *J Appl Physiol* 68(6):2627, 1990.)

Although CHF is by far the most common cause of bilateral pleural effusions, an alternate explanation should be sought if there is no cardiomegaly. In one series of 78 patients with bilateral effusions but a normal-sized heart, only 4% of the effusions were caused by CHF.¹⁶³

Diagnosis and Management

The diagnosis is usually suggested by the clinical picture of CHF. A diagnostic thoracentesis should be performed if the pleural effusion is unilateral, if bilateral effusions are not comparable in size, if the patient is febrile, if the patient has pleuritic chest pain, or if the patient does not have cardiomegaly.⁶² If none of these conditions is met, one can treat the CHF and observe; if the effusions do not resolve in a few days, a diagnostic thoracentesis should be performed.

The pleural fluid from a patient with CHF is usually a transudate.³⁷ However, if the patient has been on diuretics, the pleural fluid protein and LDH ratios may be increased sufficiently that the pleural fluid meets Light's exudative criteria. A similar phenomenon has been described in the ascites literature.¹⁶⁴ The LDH ratio can also increase if intrapleural LDH increases due to injury from repeated taps and if serum LDH falls when diuresis reduces liver congestion.¹⁶⁴ Generally, if the effusion protein and LDH values meet Light's criteria for an exudate, it is only by a small amount.⁵⁸ The transudative nature of the pleural fluids can be established in such patients if the serum minus the pleural fluid protein level is greater than 3.1 g/dL or the serum minus the pleural fluid albumin level is greater than 1.2 g/dL.⁵⁶

Measurement of pleural fluid *N-terminal pro-brain natriuretic hormone* (NT-proBNP) is useful in this setting and may be more accurate, although more expensive, than the serum-to-pleural protein gradients for correctly classifying effusions from CHF.⁵⁷ Pleural fluid NT-proBNP is superior to BNP.⁵⁷ In a systematic review and meta-analysis of 10 studies, pleural fluid NT-pro-BNP was shown to be useful for the diagnosis of pleural effusions due to CHF; the studies used different threshold values, but, in this review, the authors proposed a threshold for diagnosis of 1500 ng/mL (the average level was > 6000 pg/mL).¹⁶⁵

Patients with CHF and pleural effusion should be treated with afterload reduction, diuretics, and inotropes as needed. When heart failure is successfully managed, pleural effusion usually resolves. If the patient is markedly dyspneic when first evaluated, a therapeutic thoracentesis to relieve the dyspnea should be considered. Rarely, despite intensive therapy of the CHF, a patient has persistent large effusions; if such patients are dyspneic and if their dyspnea is relieved by a therapeutic thoracentesis, consideration can be given to controlling the effusions with a pleurodesis using a sclerosing agent, such as doxycycline or talc slurry, or the insertion of an indwelling catheter.

HEPATIC HYDROTHORAX

The incidence of pleural effusions with cirrhosis is approximately 6%.^{166,167} The incidence appears to be much higher if ascites is present; however, in some patients with hepatic hydrothorax, no ascites can be detected, presumably because all ascitic fluid moves to the pleural space due to the prevailing pressure gradients and the low-resistance diaphragmatic defects.^{39,168}

Pathophysiology

The predominant mechanism leading to a pleural effusion in a patient with cirrhosis and ascites appears to be the movement of the ascitic fluid from the peritoneal cavity through defects in the diaphragm into the pleural space.¹⁶⁹ The decreased plasma osmotic pressure is only a secondary factor.

The diaphragmatic defects have been demonstrated in many ways. Lieberman and coworkers¹⁶⁶ introduced 500 to 1000 mL of air into the peritoneal cavity of five patients with cirrhosis, ascites, and pleural effusions and found that a pneumothorax developed in all patients within 48 hours. In addition, they were able to demonstrate air bubbles coming through an otherwise undetectable diaphragmatic defect at thoracoscopy in one of their patients. In two of their patients, diaphragmatic defects were demonstrated at postmortem examination.¹⁶⁶ By thoracoscopy, different types of defects have been documented such as blebs or

fenestrations¹⁷⁰ (eFig. 79-3). There are no normal direct lymphatic connections between the peritoneal and the pleural spaces. Thus, the connections between the spaces are either preexisting developmental defects or are defects caused by trauma or stretching.

Clinical Manifestations

The clinical situation in patients with pleural effusions from cirrhosis and ascites is usually dominated by the cirrhosis and ascites. At times, however, the presence of a large pleural effusion may produce severe dyspnea. The pleural effusion associated with cirrhosis and ascites is frequently large and can occupy the entire hemithorax. The large effusions form because the diaphragmatic defect permits fluid to flow from the peritoneal cavity into the pleural cavity until the pleural pressure approaches the peritoneal pressure. The pleural effusions are usually right sided (80%) but occasionally are left sided (17%) or bilateral (3%).¹⁶⁹

Diagnosis and Treatment

The diagnosis of hepatic hydrothorax is usually easily established from the clinical picture. If doubt exists, the diagnosis can be confirmed by scanning the chest after ^{99m}Tc sulfur colloid is injected into the peritoneal cavity.¹⁷¹ Both a paracentesis and a thoracentesis should be performed to confirm that the ascites and pleural fluid are both transudates. Xiol and associates¹⁷² performed thoracentesis on 60 patients with cirrhosis and ascites. The pleural fluid analysis yielded a diagnosis other than hepatic hydrothorax in 18 (30%) including 9 spontaneous bacterial pleuritis, 2 tuberculosis, 2 adenocarcinomas, 2 parapneumonic effusions, and 3 undiagnosed exudates.¹⁷² The protein level with hepatic hydrothorax in the pleural fluid is usually higher than that in the ascitic fluid but is still below 3.0 g/dL and the LDH is low.¹⁶⁶ If the polymorphonuclear cell count is greater than 500 cells/μL, the diagnosis of spontaneous bacterial pleuritis in conjunction with spontaneous bacterial peritonitis should be considered.¹⁷³

The initial management of the pleural effusion associated with cirrhosis and ascites should be directed toward treatment of the ascites. Chest tube insertion should be avoided because the ascitic fluid will also drain through the chest tube, which can lead to significant fluid and protein losses and even fatal cardiovascular collapse.¹⁶⁸ Instead, the patient should be given a low-salt diet and treated with diuretics, usually furosemide and spironolactone.

If diet and diuretics cannot control the effusion, the treatment of choice is liver transplantation.^{168,174} Patients with hepatic hydrothorax have been found to do well after transplant, at least as well as matched cirrhotic patients without hepatic hydrothorax; however, this condition does not yet merit higher priority for transplant.¹⁷⁵ The next best approach is probably implantation of a *transjugular intrahepatic portal systemic shunt* (TIPS). TIPS is usually effective in the management of hepatic hydrothorax. Kinasevitz and Keddis¹⁶⁸ summarized the literature on 115 patients who received TIPS for refractory hepatic hydrothorax and reported that the procedure controlled the hydrothorax in 80%, but 12% of the patients developed encephalopathy. In a study of TIPS with a long follow-up, 73 patients underwent TIPS with 59% complete response at 1 month and a

21% partial response; however, hepatic encephalopathy developed in 15% and 30-day mortality was 19%. Survival was associated with the pre-TIPS *Model for End-stage Liver Disease* (MELD) score: with a MELD less than 15, median survival was 875 days, and with a MELD greater than 15, it was 180 days.¹⁷⁶ If neither TIPS nor liver transplantation is feasible, the best alternative treatment is probably VATS with closure of the diaphragmatic defects and pleurodesis. Cerfolio and Bryant¹⁷⁷ performed this procedure on 41 patients and reported a success rate of 80%. Huang and colleagues¹⁷⁸ reported success in 10 patients using a pleural or mesh onlay to repair the diaphragmatic defects. Nonetheless, as pointed out in a recent review of 77 patients, the outcome for those who cannot undergo liver transplantation or TIPS is extremely poor.^{178a}

Spontaneous Bacterial Pleuritis

Spontaneous bacterial pleuritis is, by definition, infection of a preexisting hepatic hydrothorax in which a parapneumonic infection has been excluded. Originally termed spontaneous bacterial *empyema*, we prefer the term *pleuritis* to emphasize its similarity to spontaneous bacterial peritonitis and to indicate that its treatment does not require tube thoracostomy. The diagnosis of spontaneous bacterial pleuritis is made if the pleural fluid culture is positive, the pleural fluid neutrophil count is greater than 250 cells/μL, and a pneumonic process has been excluded; the diagnosis of *culture-negative* spontaneous bacterial pleuritis is made if the pleural fluid cultures are negative and the pleural fluid neutrophil count is greater than 500 cells/μL.¹⁷³ In one series in Spain, 16 of 120 patients (13%) admitted with a diagnosis of hepatic hydrothorax had a spontaneous bacterial pleuritis; 10 of 24 episodes (43%) of spontaneous bacterial pleuritis were not associated with bacterial peritonitis.¹⁷³ Appropriate treatment of spontaneous bacterial pleuritis requires systemic antibiotics, but tube thoracostomy does not appear to be necessary. It remains to be seen whether spontaneous bacterial pleuritis is common in the United States.

NEPHROTIC SYNDROME

There is a high incidence of pleural effusion in patients with the nephrotic syndrome. In one study of 52 patients, 21% had pleural effusions.¹⁷⁹ The mechanism responsible for the transudative pleural effusion associated with the nephrotic syndrome is probably the combination of decreased plasma osmotic pressure and increased hydrostatic pressure. The increased hydrostatic pressure is due to salt retention, which produces hypervolemia. The pleural effusions in patients with a nephrotic syndrome are usually bilateral and are frequently infrapulmonary in location.¹⁷⁹

A diagnostic thoracentesis should be performed in all patients with the nephrotic syndrome and a pleural effusion to prove that the pleural fluid is a transudate. Nonetheless, the possibility of PE should always be considered in patients with the nephrotic syndrome and a pleural effusion. In one series of 36 patients with the nephrotic syndrome, 22% had pulmonary emboli.¹⁸⁰ If the pleural fluid is an exudate, a CT pulmonary angiogram should be obtained.

The treatment of the pleural effusion associated with the nephrotic syndrome should be aimed at increasing the level

of protein in the serum by decreasing the protein loss in urine. If this is unsuccessful, pleurodesis with a sclerosing agent should be considered in selected patients who are symptomatic from the pleural effusion.

PERITONEAL DIALYSIS

Peritoneal dialysis is occasionally complicated by the development of an acute hydrothorax. In a review of 3195 patients receiving continuous ambulatory peritoneal dialysis in Japan, 1.6% developed a pleural effusion as a result of the movement of the dialysate from the peritoneal cavity into the pleural cavity.¹⁸¹ The effusion developed within 30 days of initiation of the dialysis in 50% of the patients, but 18% had been receiving dialysis for more than a year before the effusion developed.¹⁸¹ The effusions are right sided in about 90%.^{181,182}

The pleural fluid in these patients is characterized by a glucose level intermediate between that of the dialysate and the serum, a protein level below 10 g/L (1.0 g/dL), and a low LDH level. The LDH level is higher and the glucose level is lower in the pleural fluid than in the ascitic fluid.¹⁸² Although the communication closes spontaneously in some patients, a surgical approach is usually required if continuous ambulatory peritoneal dialysis is to be continued. The treatment of choice is probably thoracoscopy with closure of the diaphragmatic defects, followed by pleurodesis. Alternative treatments are pleurodesis alone or thoracotomy with repair of the diaphragmatic defects.

URINOTHORAX

Obstruction of the urinary tract resulting in a retroperitoneal urine collection (urinoma) can lead to a pleural effusion.¹⁸³ The mechanism by which the pleural fluid accumulates is unknown, but it is thought that this retroperitoneal urine collection drains along pressure gradients into the pleural space. The collection of fluid actually represents urine, and the pleural fluid smells like urine. Patients with urinothoraces have pleural fluid creatinine levels higher than those in serum, but about 10% of other effusions also meet this criterion.¹⁸³ When the urinary tract obstruction is relieved, the pleural effusion rapidly disappears.^{183a}

MYXEDEMA

A pleural effusion sometimes arises as a complication of myxedema. Most patients with myxedema and pleural effusion have a concomitant pericardial effusion. In one series of 25 patients with pericardial effusions secondary to myxedema, 13 of the patients (52%) had concomitant pleural effusion.¹⁸⁴ When the pleural effusion presents at the same time as a pericardial effusion, the pleural fluid is usually a transudate.¹⁸⁴ The isolated pleural effusion seen in conjunction with myxedema is generally borderline between a transudate and an exudate. Although the mechanism of formation of the effusion is unknown, a decrease in lymphatic function due to low thyroid levels may contribute.²³ Thyroid replacement is the obvious treatment for pleural effusions associated with myxedema.

PERICARDIAL DISEASE

Pleural effusion is commonly seen in patients with pericardial disease (Video 79-3). Few of these effusions have been characterized, but they can be transudative or exudative. In one series of 35 patients with constrictive pericarditis, 60% of the patients had radiologically demonstrable pleural effusions.¹⁸⁵ Weiss and Spodick¹⁸⁶ reviewed 124 patients with pericardial disease and found that 35 (28%) had a pleural effusion. Of the 35 patients, 21 had only a left-sided pleural effusion (eFig. 79-4), 2 had only a right-sided pleural effusion, and the remaining 12 were bilateral. However, in another series of 21 patients with constrictive pericarditis and pleural effusion, the pleural effusion was right sided only in 9 (43%) and bilateral in the remaining 12 (57%).¹⁸⁵

The mechanism responsible for the pleural effusion associated with pericardial disease is not clear. In constrictive pericarditis, one explanation for the effusions is that the pulmonary and systemic capillary pressures are elevated secondary to the pericardial disease, resulting in a transudative pleural effusion. However, one would expect these effusions to be bilateral. In inflammatory pericardial disease, however, the pleural effusion tends to be left sided (see eFig. 79-4) and, although the characteristics of the fluid have not been well described, it is probable that the effusion forms from extension of the pericardial inflammation to the adjacent pleura¹⁸⁶ or possibly from direct movement of the fluid across the pericardium into the pleural space.

OTHER CAUSES OF TRANSUDATIVE PLEURAL EFFUSIONS

A subarachnoid pleural fistula can develop, resulting in the accumulation of *cerebrospinal fluid* (CSF) in the pleural space. The pleural fluid looks like CSF with low protein and LDH levels. Subarachnoid pleural fistula can follow ventriculo-pleural shunting and with penetrating injuries, fractures, or surgery of the thoracic spine.⁶² If there is doubt about the diagnosis, measurement of the pleural fluid β_2 -transferrin is useful because only CSF contains this molecule.¹⁸⁷ The fistula rarely closes without surgical intervention.

Central venous obstruction can cause large, persistent transudative effusions, perhaps due to increases in venous pressure leading to increased formation of liquid and to decreases in lymphatic clearance. Venous obstruction as a cause of persistent transudative effusions should be considered in situations with prior instrumentation and has been reported from occlusions of the hemiazygos vein, brachiocephalic vein, and superior vena cava (eFig. 79-5). Relief of the obstruction can lead to resolution of the effusion.¹⁸⁸

Pulmonary veno-occlusive disease frequently has small pleural effusions.¹⁸⁹ The characteristics of the pleural fluid have not been described, but it is probably a transudate because the effusions are likely related to the increased pulmonary interstitial fluid. Patients with right failure secondary to pulmonary hypertension frequently have small bilateral pleural effusions.¹⁹⁰

PE has been reported to be associated with a transudative pleural effusion. However, in a study of the pleural fluid findings in patients with PE, all 60 pleural fluids were exudates.⁷⁴ Pleural amyloidosis is associated with transudative

effusions, probably due to a combination of heart failure and pleural infiltration with amyloid.¹⁹¹ Cytokines such as *vascular endothelial growth factor* (VEGF) may play a role because, in one series, three out of four patients with persistent pleural effusions due to primary systemic amyloid improved with treatment with an antibody against VEGF, bevacizumab.¹⁹²

EXUDATIVE PLEURAL EFFUSIONS

Exudative pleural effusions are common clinical problems. These effusions may develop as a result of inflammation, injury, or malignancy, which can involve the pleural surfaces, the adjacent lung, or more distant tissues, such as mediastinal or abdominal organs. Further discussion of effusions due to infections is presented in Chapter 80; special types of effusions (chylothorax and hemothorax) are discussed in Chapter 81; and effusions secondary to pleural tumors are presented in Chapter 82.

PULMONARY EMBOLISM

The diagnosis most commonly overlooked in the differential diagnosis of a patient with an undiagnosed pleural effusion

is PE. It has been estimated that at least 500,000 persons develop venous thromboembolism annually in the United States. Because at least 30% of patients with PE have an associated pleural effusion,¹⁹³ more than 150,000 pleural effusions secondary to PE should be diagnosed annually. Therefore, one should expect to see more cases of pleural effusion secondary to PE than to bronchogenic carcinoma. Nevertheless, in most large series, PE accounts for less than 5% of pleural effusions. The diagnosis and treatment of PE are discussed in Chapter 57.

Clinical Manifestations

Patients with PE can be divided into three categories, depending on their presenting symptoms: (1) pleuritic pain or hemoptysis, (2) isolated dyspnea, and (3) circulatory collapse. In the *Prospective Investigation of Pulmonary Embolism Diagnosis* (PIOPED) study, 56% of the patients with pleuritic pain or hemoptysis had pleural effusion and 26% of those with isolated dyspnea had pleural effusion, but none of the patients with circulatory collapse had pleural effusion.¹⁹³

Approximately 50% of patients with paraembolic effusions have parenchymal opacities seen on chest radiographs.¹⁹⁴ The opacities are usually in the lower lobes, are pleural based, and are convex toward the hilum. Paraembolic effusions are usually small (Fig. 79-7); in one series,

Figure 79-7 Pleural effusion related to acute pulmonary embolism. **A**, Axial CT pulmonary angiography shows bilateral acute pulmonary emboli (arrows); a trace left pleural effusion (double arrowheads) is present. **B**, Frontal chest radiograph obtained 5 days following the CT pulmonary angiogram (**A**) shows left basal consolidation with a large left pleural effusion. **C**, Axial CT pulmonary angiography performed more than 1 month after presentation, during treatment, shows near-complete resolution of the bilateral pulmonary emboli (arrow). **D**, Frontal chest radiograph obtained more than 1 month after presentation shows complete resolution of the left basal consolidation and pleural effusion. (See also [Video 79-4A](#) and [B](#).) (Courtesy Michael Gotway, MD.)

48 of 56 patients (86%) had only blunting of the costophrenic angle, and no patient had an effusion that occupied more than one third of a hemithorax.¹⁹³ The pleural effusions may be unilateral or bilateral. In one study of 63 patients with PE and pleural effusion, the effusions were bilateral in 16 (25%).¹⁹⁵ Interestingly, in studies using *CT pulmonary angiography* (CTPA) in patients suspected of having PE, those patients found to have PE were no more likely to have pleural effusions than those without embolism (50% vs. 58%¹⁹⁶; 57% vs. 56%¹⁹⁷). In another study using CTPA, those found to have PE were more likely to have pleural effusions (29/60 or 48%) than those without PE (76/225 or 34%); effusions tended to be small and few were large enough to warrant thoracentesis. Of note, effusions in those without PE were also common and similar to those in size and location to those in patients with PE.¹⁹⁸ Patients suspected of having PE likely have other underlying conditions that predispose them to pleural effusions, such as CHF or pneumonia.

Pleural fluid analysis is of limited value in establishing the diagnosis of paraembolic effusion because there is nothing characteristic about the fluid. The pleural fluid is almost always an exudate.⁷⁴ The pleural fluid red blood cell count exceeds 100,000/ μ L in less than 20% and is below 10,000/ μ L in at least 30%. The pleural fluid white blood cell count can vary from less than 100 to more than 50,000/ μ L. The differential white blood cell count may reveal predominantly polymorphonuclear leukocytes, eosinophils, or mononuclear cells.

Diagnosis

The diagnosis of PE is discussed in Chapter 57. The possibility of PE should be considered in every patient with a pleural effusion, even if the patient has obvious CHF. In an autopsy series of 290 patients with CHF and pleural effusion, 60 (21%) had PE.¹⁶⁰ When a paraembolic effusion is strongly suspected, the patient should be started on heparin treatment and a diagnostic test for PE should be performed before a thoracentesis is attempted.¹⁸⁹

In the patient with an undiagnosed pleural effusion for whom PE is suspected, CTPA appears to be the preferred test because it also provides information about the lung parenchyma, the mediastinum, and the pleural surfaces, which may provide clues to the etiology of the pleural effusion (see

Fig. 79-7) (Videos 79-4A and 79-4B). Another reason to obtain the CTPA rather than a perfusion scan in patients with pleural effusions suspected of having PE is that the presence of the effusion makes the lung scan more difficult to interpret.

Treatment

Treating the patient with a paraembolic effusion is the same as for any patient with PE (see Chapter 57). The presence of bloody pleural fluid is not a contraindication to the administration of heparin or, if indicated, thrombolytic therapy.¹⁹⁴ Paraembolic effusions usually reach their maximum size within the first 3 days.¹⁹⁹ If the effusion increases in size after this time, the patient probably has recurrent emboli, a pleural infection, or a hemothorax and a diagnostic thoracentesis should be performed. If the pleural fluid hematocrit value is greater than 50% of the peripheral hematocrit, a hemothorax is present. In this

instance, anticoagulation should be discontinued and tube thoracostomy should be performed.

ABDOMINAL DISEASES

Many abdominal diseases can cause pulmonary signs and symptoms. This section describes the most important of these disorders that cause pleural effusion.

Esophageal Perforation

The diagnosis of esophageal rupture should always be considered in the differential diagnosis of exudative pleural effusions because, if this condition is not rapidly treated, the mortality increases, with current estimates ranging between 30% and 60%. Approximately 60% of patients with esophageal perforation have a pleural effusion, whereas about 25% have a pneumothorax.²⁰⁰ The pleural effusion is usually left sided (Fig. 79-8), but it may be right sided or bilateral.

The esophagus most commonly perforates as a complication of esophagoscopy and is more likely when there is an attempt to remove a foreign body or to dilate an esophageal stricture.²⁰¹ Overall, the incidence of esophageal perforation with esophagoscopy examination is 0.15% to 0.70%.²⁰⁰ The insertion of a Blakemore-Sengstaken tube for esophageal varices can be complicated by esophageal rupture. Frequently, the diagnosis is missed in these patients because of the severity of their illness and the multiple coexisting problems.²⁰⁰ Esophageal perforation may also result from transesophageal echocardiography, foreign bodies, esophageal carcinoma, gastric intubation, chest trauma, chest surgery, or vomiting (Boerhaave syndrome). In a review of 120 consecutive patients with esophageal perforation from all causes, the incidence of pleural effusion was 52% and of pneumothorax, 11%.²⁰²

Figure 79-8 Effusion due to esophageal perforation. Axial CT through the lower thorax in a patient with chest pain shows pneumomediastinum (small arrowheads) and leakage of water-soluble oral contrast from the ruptured esophagus (large arrowheads) through the mediastinum into the left pleural space (arrow). (From Fadoo F, Ruiz DE, Dawn SK, et al: Helical CT esophagography for the evaluation of suspected esophageal perforation or rupture. *AJR Am J Roentgenol* 182:1177–1179, 2004.)

Clinical Manifestations. The symptoms associated with esophageal perforation result from the acute mediastinitis produced by contamination of the mediastinum by the oropharyngeal contents. Most of the morbidity from esophageal perforation is caused by infection of the mediastinum and the pleural space by the oropharyngeal bacterial flora.¹⁰⁹

A patient with an esophageal perforation is usually acutely ill. With a spontaneous rupture, there is frequently a sensation of tearing or bursting in the lower part of the chest or the epigastrium. The chest pain is characteristically excruciating and is often unrelieved by opiates. More than 50% of patients have small amounts of hematemesis. The presence of subcutaneous emphysema in the suprasternal notch is suggestive of the diagnosis. However, less than 10% of patients have subcutaneous emphysema within the first 4 hours of rupture.²⁰³ When the esophagus is perforated during esophagoscopy, the endoscopist generally does not realize it; however, the patients usually develop persistent chest or epigastric pain within a few hours after the procedure.

Diagnosis. The diagnosis of esophageal rupture should be considered in all acutely ill patients with an exudative pleural effusion. The best screening test for esophageal rupture appears to be the level of amylase in the pleural fluid.²⁰³ The pleural fluid amylase level is elevated owing to saliva, with its high amylase content, entering the pleural space.¹⁰⁸ The pleural fluid pH is usually decreased below 7.00 in patients with pleural effusion secondary to esophageal perforation due to the intense inflammatory response resulting from the mediastinitis and not the regurgitation of gastric juice into the pleural space. The demonstration of either squamous epithelial cells or food particles in the pleural fluid is highly suggestive of the diagnosis. Other findings suggestive of esophageal rupture are a chest tube output more than 500 mL/day and polymicrobial flora in the pleural fluid. The diagnosis is established when esophageal perforation is confirmed by contrast studies of the esophagus (see Fig. 79-8).

Treatment. Treatment of the esophageal rupture may range from nonoperative stenting to primary repair to esophagectomy depending on the underlying disease of the esophagus and the size of the rupture.²⁰² Mediastinitis from esophageal perforation and other causes is discussed in detail in Chapter 84.

Pancreatic Disease

Three different types of nonmalignant pancreatic disease can have an accompanying pleural effusion: acute pancreatitis, chronic pancreatitis with pseudocyst, and pancreatic ascites.

Acute Pancreatitis. In a study of 133 patients with their first attack of acute pancreatitis, 50% of the patients had a pleural effusion on chest CT scan.²⁰⁴ The effusion was bilateral in 51 (77%), unilateral left sided in 10 (15%), and unilateral right sided in 5 (8%). Patients with acute pancreatitis and a pleural effusion had more severe disease and a higher mortality rate than did those without effusions.²⁰⁴ The exudative pleural effusion accompanying acute pancreatitis results from the diaphragmatic inflammation and

transdiaphragmatic transfer of the exudative fluid arising from acute pancreatic inflammation.

The clinical picture is usually dominated by abdominal symptoms, including pain, nausea, and vomiting. However, at times, respiratory symptoms consisting of pleuritic chest pain and dyspnea may dominate the clinical picture. In addition to the small to moderate-sized pleural effusion, the chest radiograph may reveal an elevated diaphragm and basilar opacities. Demonstration of an elevated pleural fluid amylase level is highly suggestive of the diagnosis, but the diagnosis of esophageal rupture must be excluded. The pleural fluid is an exudate with predominantly polymorphonuclear leukocytes and a normal glucose level.

Chronic Pancreatic Pleural Effusion. Patients with chronic pancreatic disease sometimes have a large chronic pleural effusion. When the pancreatic ductal system is disrupted, a pseudocyst may form in the pancreas. A sinus tract may extend from the pseudocyst through the aortic or esophageal hiatus into the mediastinum. Once the sinus tract reaches the mediastinum, the process may be contained to form a mediastinal pseudocyst or it may rupture into one or both pleural spaces, resulting in a large chronic pleural effusion¹¹⁰ (Fig. 79-9).

The clinical picture of patients with chronic pancreatic disease and pleural effusion is usually dominated by chest symptoms, such as dyspnea, cough, and chest pain. Most patients do not have abdominal symptoms because the pancreaticopleural fistula decompresses the pseudocyst. The pleural effusion is usually massive and recurs rapidly after thoracentesis.¹¹⁰ The effusion is usually left sided but may be right sided or bilateral.

The key to the diagnosis is a markedly elevated pleural fluid amylase level, generally greater than 1000 IU/mL, while the serum level of amylase may be only mildly elevated. Patients with chronic pancreatic pleural disease are generally easily differentiated from those with malignant pleural effusion, who also may have an elevated pleural fluid amylase level, because the amylase level is much higher with the pseudocyst. In rare cases in which the differentiation is not obvious, the diagnosis can be made by measuring amylase isoenzymes because the amylase

Figure 79-9 Effusion due to pancreatic pseudocyst. Axial CT image through the lower thorax in a patient with chronic pancreatitis shows bilateral pleural effusions (E) and a cystic mass in the mediastinum (arrows) representing a pseudocyst.

associated with malignancy is of the salivary, not the pancreatic, type.¹¹² Both ultrasound and CT are useful in establishing the diagnosis of pancreatic pseudocyst. Endoscopic retrograde cholangiopancreatography usually documents the fistulous tract or other pancreatic pathology.

Patients with chronic pancreatic pleural effusions should be given a trial of conservative therapy for 2 to 3 weeks that consists of nasogastric suction, no oral intake, suppression of pancreatic secretion with atropine, and repeated therapeutic thoracenteses.¹¹⁰ The administration of a continuous infusion of somatostatin may decrease the secretions through the fistula and facilitate closure.²⁰⁵ Conservative treatment is successful within 4 weeks in about 40% of patients. If conservative treatment fails, a laparotomy should be performed. The anatomy of the pancreatic ductal system should be assessed before surgery with endoscopic retrograde cholangiopancreatography or at the time of operation with operative pancreatography. If a sinus tract is found, it should be ligated or excised. The pancreas should be partially resected, drained with a Roux-en-Y loop, or both, depending on the pancreatographic findings.¹¹⁰ An alternative approach is to attempt percutaneous abdominal pseudocyst drainage by use of CT guidance. Decortication of the pleura may be necessary for some patients in order to remove the thick pleural peel created by the intense inflammation caused by the presence of pancreatic enzymes.

Pancreatic Pleural Effusion. Some patients with pancreatic disease develop ascites characterized by high amylase and protein levels. If such patients should happen to have or develop a defect in their diaphragm, they develop a large pleural effusion as a result of the flow of fluid from the peritoneal cavity to the pleural cavity. The treatment for pancreatic pleural effusion is the same as for pancreatic ascites, except serial thoracenteses rather than serial paracenteses are performed.

Intra-Abdominal Abscesses

Pleural effusions are frequently seen with intra-abdominal abscesses. The possibility of an intra-abdominal abscess should be considered strongly in any patient with an undiagnosed exudative pleural effusion containing predominantly polymorphonuclear leukocytes, particularly when there are no pulmonary parenchymal opacities. The mechanism responsible for the development of the exudative pleural effusion is probably diaphragmatic irritation.

Subphrenic abscess is the intra-abdominal abscess most commonly associated with a pleural effusion; pleural effusions develop in approximately 80% of patients with subphrenic abscess.²⁰⁶ The approximate incidence of effusions with other intra-abdominal abscesses is 40% in pancreatic abscesses, 30% in splenic abscess, and 20% in intrahepatic abscesses. With pancreatic abscess, the pleural fluid has a high amylase level.

Clinical Manifestations. Subphrenic abscess most commonly develops as a postoperative complication 1 to 3 weeks after intra-abdominal surgery.²⁰⁶ Splenectomy and gastrectomy are particularly likely to be complicated by left subphrenic abscess. There is no antecedent abdominal

surgery in approximately 10% of patients with subphrenic abscess.²⁰⁶ The abscess may result from perforation of the stomach, duodenum, appendix, colon, or a diverticulum, or from diverticulitis, cholecystitis, pancreatitis, or trauma. Most patients have fever, leukocytosis, and abdominal pain but, frequently, there are no localizing signs or symptoms.

Most patients with pyogenic intrahepatic abscesses have fever and anorexia. Abdominal pain is common and often not localized to the right upper quadrant. On physical examination, an enlarged, tender liver can be demonstrated. Laboratory tests reveal leukocytosis, anemia, elevated alkaline phosphatase levels, and hyperbilirubinemia.²⁰⁷

Pancreatic abscess usually follows an episode of acute pancreatitis. This diagnosis should be suspected if the patient does not respond to the initial therapy or if fever, abdominal pain, and leukocytosis develop within 3 weeks of the episode of acute pancreatitis. Splenic abscess is uncommon, usually seen in patients with systemic infection. Bacterial endocarditis is the most common underlying infection.

The pleural fluid that accumulates in patients with intra-abdominal abscesses is an exudate with predominantly polymorphonuclear leukocytes. The pleural fluid white blood cell count may exceed 50,000/ μ L, but the pleural fluid pH and glucose concentration usually remain above 7.20 and 60 mg/dL (3.33 mmol/L), respectively. Only rarely does the pleural fluid become infected.

Diagnosis and Treatment. The diagnosis of intra-abdominal abscess is best established with an abdominal CT scan (eFig. 79-6 and Video 79-5).²⁰⁸ The appropriate treatment for a patient with an intra-abdominal abscess and a pleural effusion is drainage of the abscess combined with parenteral antibiotics.

Abdominal Surgery

Approximately 50% of patients undergoing abdominal surgery develop a pleural effusion in the first few days after surgery.^{209,210} The incidence of postoperative pleural effusion is greater in patients undergoing upper abdominal surgery, in patients with postoperative atelectasis, and in patients with free abdominal fluid at surgery.^{209,210} The accumulation of pleural fluid within the first 72 hours after abdominal surgery is probably related to either diaphragmatic irritation or transdiaphragmatic movement of intra-abdominal fluid. A postoperative patient with a significant amount of pleural fluid, particularly when associated with fever, should have a diagnostic thoracentesis to rule out pleural infection as a cause of the effusion. In addition, the possibility of PE should be considered. If the effusion develops more than 72 hours after surgery, it is probably not related to the surgical procedure itself, and alternative explanations must be sought, such as PE intra-abdominal abscess, and hypervolemia.

Liver Transplantation

Most patients who undergo an orthotopic liver transplantation develop a pleural effusion after surgery. In one study, 68% of 300 patients undergoing liver transplantation developed a pleural effusion and the effusion occupied more than 25% of the hemithorax in 21 patients (7%).²¹¹ The

effusion was unilateral right sided in 153 and bilateral in 53. The effusions are large enough to require therapeutic thoracentesis or tube thoracostomy in approximately 10%.²¹¹ The natural history of these effusions is that they increase in size over the first 3 postoperative days and then gradually resolve over several weeks to several months. The pathogenesis of these effusions is probably related to injury or irritation of the right hemidiaphragm caused by the extensive right upper quadrant dissection. These pleural effusions can be largely prevented if a fibrin sealant is sprayed on the undersurface of the diaphragm around the insertion of the liver ligaments at the time of the transplantation.²¹²

Bilious Pleural Effusion

Bilious pleural effusions are due to a fistula from the biliary tree to the pleural space.²¹³ The fistula may be secondary to trauma, suppurative complications of biliary tract infections, or surgery, particularly when biliary obstruction is present. The diagnosis should be suspected in any patient with an obstructed biliary tract. The pleural fluid usually appears bilious but, at times, the diagnosis may depend on the demonstration that the ratio of pleural fluid to serum bilirubin is greater than 1.0. Appropriate treatment consists of reestablishment of biliary drainage. The incidence of empyema with bilious pleural effusion is approximately 50%. Most patients who have a bilious pleural effusion require decortication and diaphragmatic repair.⁶²

INFLAMMATORY DISEASES

Rheumatoid Pleuritis

The pleura is occasionally involved in the course of rheumatoid arthritis. Approximately 5% of patients with rheumatoid arthritis have a pleural effusion, and approximately 20% experience pleuritic chest pain.^{113,214} Rheumatoid pleurisy has a striking male predominance, despite the higher prevalence of rheumatoid disease in women; more than 10% of men, but less than 2% of women, with rheumatoid disease have a pleural effusion.^{113,214}

Clinical Manifestations. Almost all patients with rheumatoid pleural effusions are older than 35 years. Approximately 80% are men and approximately 80% have subcutaneous nodules. The pleural effusion usually develops only after the arthritis has been present for several years¹¹³ but, on rare occasions, a patient may present with a pleural effusion.

Patients with rheumatoid pleuritis may be asymptomatic or symptomatic with pleuritic chest pain, fever, or both,^{113,118} and some patients experience dyspnea secondary to the presence of pleural fluid. In most patients, the chest radiograph reveals a small or moderate-sized pleural effusion. In approximately 25% of patients, the effusion is bilateral.¹¹³ With time, the effusion may alternate from one side to the other or come and go on the same side. Other intrathoracic manifestations of rheumatoid disease are present in up to one third of patients.¹¹³

Diagnosis. The diagnosis is suggested by the clinical picture of rheumatoid arthritis and the presence of a pleural

effusion. The pleural fluid with rheumatoid pleuritis is distinctive, characterized by a glucose level less than 30 mg/dL (1.67 mmol/L), a high LDH level (>2 times the upper limit of normal), a low pH (<7.20), and a high rheumatoid factor titer (>1 : 320 and ≥ the serum titer).¹¹⁸ Occasionally, the pleural fluid glucose is not low when the patient is first seen, but serial pleural fluid glucose determinations reveal progressively lower pleural fluid glucose levels. Another interesting characteristic of rheumatoid pleural effusions is their tendency to contain cholesterol crystals or high levels of cholesterol.²¹⁵ A unique cytologic appearance of elongated macrophages, called “comet tail” cells, is also considered specific for the diagnosis²¹⁶ (eFig. 79-7).

With the characteristic pleural fluid findings, the primary alternative diagnosis to exclude is complicated parapneumonic effusion. The incidence of complicated parapneumonic effusion is high in patients with rheumatoid pleuritis,²¹⁷ so this differentiation is important. It is particularly important to examine the Gram stain of the pleural fluid and to culture the fluid both aerobically and anaerobically.

Prognosis and Treatment. The natural history of rheumatoid pleuritis varies. Most patients experience a spontaneous resolution within 3 months but, in the occasional patient, the effusion is persistent and massive pleural thickening may develop. No studies have demonstrated that anti-inflammatory therapy has any influence on the course of rheumatoid pleuritis. The results after intrapleural corticosteroids have been mixed.⁶² Decortication should be considered in patients with thickened pleura who are symptomatic with dyspnea. This procedure is particularly difficult in patients with rheumatoid pleuritis because it is not easy to develop a plane of dissection between the lung and the fibrous peel.

Lupus Pleuritis

Approximately 40% of patients with SLE or drug-induced lupus have a pleural effusion during the course of their disease.¹¹⁴

Clinical Manifestations. Most patients with lupus pleuritis have arthritis or arthralgias before the development of a pleural effusion. Almost all patients with lupus pleuritis have pleuritic chest pain, and most are also febrile. Lupus pleuritis frequently develops in association with an exacerbation of the underlying disease. The pleural effusions secondary to lupus are usually small and bilateral in about 50% of patients.²¹⁸

Many medications have been incriminated for producing drug-induced lupus erythematosus (see Chapter 71).⁶² Hydralazine, procainamide, isoniazid, phenytoin, and chlorpromazine are the ones most commonly associated with drug-induced lupus, but there are more than 70 other drugs that possibly induce lupus. For the latest information on possible drug reactions, including lupus reactions, an excellent online source is www.pneumotox.com. The presenting signs, symptoms, and radiographic abnormalities are similar, whether the pleuritis is due to spontaneous or to drug-induced lupus. The symptoms associated with drug-induced lupus characteristically abate within days of discontinuing the offending drug.

Diagnosis. The possibility of lupus pleuritis should be considered in any patient with an exudative pleural effusion of unknown cause. The pleural fluid can contain a predominance of either polymorphonuclear or mononuclear cells, depending on the timing of the thoracentesis in relation to the development of the symptoms.⁶⁴ Although it was believed in the past that elevated ANA titers in the pleural fluid were diagnostic of lupus pleuritis, it appears that such elevated titers are neither specific nor sensitive for diagnosing lupus pleuritis.^{115,219} The diagnosis is based primarily on the clinical picture and the serologic findings for lupus.

Treatment. In contrast to rheumatoid pleuritis, the pleuritis with systemic lupus responds to corticosteroid administration. It is recommended that patients with lupus pleuritis be treated with oral prednisone, with rapid tapering once the symptoms are controlled. At times, the effusion is large, is symptomatic, and does not respond to corticosteroid therapy. In such a situation, consideration should be given to chemical pleurodesis. Of course, if the patient has drug-induced lupus, the offending drug should be withdrawn.

OTHER INFLAMMATORY DISEASES

Pleural effusions occasionally develop in the course of eosinophilic granulomatosis with polyangiitis (Churg-Strauss), granulomatosis with polyangiitis (Wegener), and Sjögren syndrome, which are described in detail in other chapters. The pleural disease seen with these diseases constitutes a relatively minor portion of the clinical picture.

SARCOIDOSIS

The prevalence of pleural effusion with sarcoidosis (see Chapter 66) is about 1%.^{220,221} Patients with pleural effusion due to sarcoid usually have extensive parenchymal sarcoidosis and, frequently, extrathoracic sarcoidosis.²²⁰ The symptoms of pleural involvement with sarcoidosis vary; many patients have no symptoms, although an equal number have pleuritic chest pain or dyspnea.

The pleural effusions with sarcoidosis are usually small and are bilateral in approximately one third of cases. The pleural fluid is almost always an exudate, and its cell differential is characterized by predominantly small lymphocytes.^{220,221} In the patient with known sarcoidosis, one can attribute the presence of the pleural effusion to sarcoid only when other causes of exudative lymphocyte-predominant pleural effusions, such as tuberculosis, are excluded. The pleural effusion secondary to sarcoidosis may resolve spontaneously, or corticosteroid therapy may be required for its resolution.

ASBESTOS EXPOSURE

An otherwise unexplained pleural effusion may result years after exposure to asbestos, which may have been brief or intermittent, and in the immediate or distant past. Epler and coworkers²²² reviewed the medical histories of 1135 asbestos workers whom they had followed for several years and found that 35 (3%) of the workers had pleural effusions for

which there was no other ready explanation. The heavier the asbestos exposure, the more likely the patient is to develop a pleural effusion. The pleural effusion sometimes develops within 5 years of the initial exposure but, in one large series, the mean latency was 30 years.²²³

The pathogenesis of the pleural effusion arising after asbestos exposure is unknown.¹⁰ Asbestos fibers, both long and short, move from the lung to the pleural space and lodge in the parietal pleura, where they appear to be concentrated in specific locations that correlate with the lymphatic drainage. Their presence leads to a continuous low-grade inflammation. This chronic inflammation can both decrease the lymphatic clearance of the pleural space and increase the permeability of the capillaries in the parietal pleura; the combined effects could lead to the development of an exudative pleural effusion. An immune mechanism also has been invoked to explain the fluctuations in the degree of pleuritis with time.²²³

Clinical Manifestations. Patients with pleural effusion secondary to asbestos exposure have surprisingly few symptoms. In the series of Epler and coworkers,²²² 66% had no symptoms. The chest radiograph usually reveals a small to moderate-sized effusion, which is bilateral in about 10%. The pleural fluid is an exudate, and the pleural fluid differential can reveal either predominantly polymorphonuclear leukocytes or mononuclear cells. Interestingly, pleural fluid eosinophilia was present in 15 (52%) of the 29 patients with asbestos pleural effusions for whom pleural fluid differentials were reported.⁷⁰

Diagnosis. The diagnosis of benign asbestos effusion is one of exclusion. It requires the following criteria: history of direct or indirect exposure to asbestos; exclusion of other causes, notably infection, PE, and malignancy; and follow-up of at least 2 years to verify that the effusion is benign.²²³

The possibility of mesothelioma must be carefully considered and excluded, a process that may include thoracoscopic examination and biopsy (see [Video 82-4](#)). 

Prognosis. The natural history of the patient with an asbestos pleural effusion is one of chronicity, with frequent recurrences and sometimes the development of extensive fibrosis of the parietal pleura.²²² On average, the pleural effusion persists for 3 months but eventually clears and leaves no residual pleural disease. Massive pleural fibrosis develops in about 20% of patients, with ipsilateral blunting of the costophrenic angle in another 20%.²²² Rounded atelectasis also develops in about 10% of patients. There is no known treatment for asbestos pleural effusion. Further information about asbestos-induced lung disease is provided in Chapter 73.

UREMIA

Uremia may be complicated by a fibrinous pleuritis and pleural effusion.⁶² The pathogenesis of the pleural effusion associated with uremia is unclear. It is probably somewhat analogous to that for uremic pericarditis because more than half of the patients with uremic pleuritis also have uremic pericarditis ([eFig. 79-8](#)). The incidence of pleural effusions with uremia is approximately 3%. A close relationship does

not appear to exist between the degree of uremia and the development of a pleural effusion. The incidence of pleural effusion in patients who are receiving chronic hemodialysis is approximately 50% on chest CT scan. The etiologies of 100 effusions seen in hospitalized patients with uremia on hemodialysis in one study were as follows: heart failure, 46; uremia, 16; parapneumonic, 15; atelectasis, 11; and miscellaneous, 12.²²⁴ In another study of 76 patients with effusions on hemodialysis, uremia was considered the cause in 24%, while parapneumonic effusion (24%) and CHF (20%) were also common.²²⁵

The pleural effusion seen with uremia frequently occupies more than 50% of the hemithorax and is bilateral in about 20% of patients.²²⁶ More than 50% of patients are symptomatic from the pleural disease, with fever (50%), chest pain (30%), cough (35%), and dyspnea (20%) being the most common symptoms. The pleural fluid is an exudate that is frequently serosanguineous or bloody. The differential white blood cell count reveals predominantly lymphocytes.²²⁶ Pleural biopsy specimens invariably reveal chronic fibrinous pleuritis.

The diagnosis of uremic pleuritis is one of exclusion in the patient with chronic renal failure. After beginning dialysis, the effusion gradually disappears within 4 to 6 weeks in about 75% of patients. In the remaining patients, the effusion persists, progresses, or recurs. An occasional patient develops marked pleural thickening that may require decortication.

POST-CARDIAC INJURY SYNDROME

Post-cardiac injury syndrome (PCIS), also known as the post-pericardiectomy or the post-myocardial infarction (Dressler) syndrome, is characterized by combinations of pericarditis, pleuritis, and pneumonitis that develop after injury to the myocardium or pericardium.^{227,228} In one report, noncomplicated PCIS was defined as the presence of temperature greater than 100.5° F, patient irritability, pericardial friction rub, and a small pericardial effusion with or without pleural effusion following cardiac trauma; a complicated PCIS was defined as a noncomplicated PCIS plus the need for hospital readmission with or without the need for pericardiocentesis or thoracentesis.²²⁹ Imazio and colleagues²³⁰ have defined the PCIS as the presence of at least two of the following: fever without alternative explanation, pleuritic chest pain, pericardial friction rub, new or worsening pleural effusion, and new or worsening pericardial effusion. PCIS has been described after myocardial infarction (eFig. 79-9), cardiac surgery, blunt chest trauma, percutaneous left ventricle puncture, and implantation of a pacemaker.²²⁷ The incidence of PCIS is approximately 1% after myocardial infarction and is somewhat higher after cardiac surgery.⁶² The exact pathogenesis of this syndrome is unknown, but it appears to have an immunologic basis.

Clinical Manifestations. The syndrome typically develops about 3 weeks after the injury, but it can happen any time between 3 days and 1 year. The two cardinal symptoms are fever and chest pain. The chest pain often precedes the onset of fever and can vary from an agonizing crush to a dull ache. At times, it may have a pleuritic component. Most patients have a pericardial friction rub. Pulmonary opacities are present in about 50% of patients, and laboratory

evaluation reveals leukocytosis with an elevated erythrocyte sedimentation rate.

A pleural effusion arises in about two thirds of patients with PCIS.²²⁷ The pleural effusions are bilateral and small in most patients. The pleural fluid is an exudate that is frequently serosanguineous or bloody. The pleural fluid differential may reveal either predominantly polymorphonuclear leukocytes or mononuclear cells, depending on the acuteness of the process.²²⁷

Diagnosis. The diagnosis of PCIS should be considered in any patient who develops a pleural effusion after injury to the heart. The diagnosis of the syndrome is established by the clinical picture and by excluding CHF, PE, and pneumonia.

Treatment. PCIS usually responds to treatment with anti-inflammatory agents, such as aspirin, colchicine or indomethacin. Corticosteroids may be necessary in more severe cases.

POST-CORONARY ARTERY BYPASS SURGERY

More than 600,000 patients undergo CABG surgery in the United States each year. Because approximately 10% of patients who undergo CABG surgery will develop a pleural effusion that occupies more than 25% of their hemithorax in the subsequent month,²³¹ CABG surgery is one of the more common causes of pleural effusions in the United States. The prevalence of small pleural effusions is high following CABG surgery. In one study, the prevalence of pleural effusions in 47 patients as detected by ultrasound was 89% at 7 days, 77% at 14 days, and 57% at 30 days.²³² In a study of 349 patients post-CABG, the prevalence of pleural effusion on chest radiograph 30 days postoperatively was 62%; and 40 of the 349 patients (11%) had an effusion that occupied more than 25% of the hemithorax.²³¹ The pleural effusions after CABG surgery tend to be left sided or bilateral and, if bilateral, the effusion is usually larger on the left.²³¹

The primary symptom of a patient with a large pleural effusion post-CABG is dyspnea.²³¹ The presence of either chest pain or fever should alert the physician to an alternative diagnosis. When all patients with large pleural effusions after CABG surgery are considered, the effusions can be divided into those that are bloody and those that are serous. The bloody effusions are probably secondary to bleeding into the pleural space. They reach their maximal size within 30 days of surgery, are frequently associated with pleural fluid or peripheral eosinophilia or both, have a high pleural fluid LDH level,²³³ and respond to one or two therapeutic thoracenteses.²³³ In contrast, the cause of the serous pleural effusions is unknown. They tend to reach their maximal size more than 30 days after surgery, have more than 50% small lymphocytes, and have a relatively low pleural fluid LDH level.²³³ Most of these late effusions can also be managed with one or two therapeutic thoracenteses,²³¹ but some are refractory. It is unknown whether anti-inflammatory agents or diuretics are beneficial in the treatment of these effusions. A placebo-controlled, double-blind randomized study of 360 patients compared the effectiveness of colchicine with placebo in preventing postoperative effusions.²³⁴ These investigators reported that the patients

who received colchicine had a significantly lower incidence of pleural effusion (12.2% vs. 26.5%) and a significantly lower incidence of pericardial effusion (12.8% vs. 22.8%).

FONTAN PROCEDURE

With the Fontan procedure, an anastomosis is created between the superior vena cava, the right atrium, or the inferior vena cava and the pulmonary artery to bypass the right ventricle, usually because of tricuspid atresia or a univentricular heart. Pleural effusion develops in many patients after surgery and contributes significantly to postoperative morbidity. Pleural effusions are more likely in patients who have significant aortopulmonary collateral vessels before surgery; thus, Spicer and colleagues²³⁵ recommended that these vessels be embolized during preoperative angiography. The amount of pleural drainage postoperatively is decreased by about 50% if the Fontan circuit is fenestrated to allow shunt of deoxygenated blood to the systemic circulation.²³⁶ After the Fontan procedure, the pleural fluid is generally an exudate; some are chylothoraces. The treatment of choice for these effusions is usually insertion of a pleuroperitoneal shunt. Alternative treatments are creation of a late fenestration to create a right-to-left shunt or chemical pleurodesis.

DRUG REACTIONS

Lupus-like syndromes arise in conjunction with the administration of many different medications and have been discussed earlier in this chapter and in Chapter 71. Although there are case reports of pleural disease associated with administration of many drugs,²³⁷ the following drugs are known to induce pleural disease.

Nitrofurantoin

Pleuropulmonary reactions occasionally result from the administration of nitrofurantoin. Such reactions can have an acute or a chronic presentation.²³⁸ The acute presentation is seen within 1 month of initiation of therapy and is manifested by dyspnea, nonproductive cough, and fever. About 20% of patients have pulmonary opacities and an effusion, and about 3% have only an effusion. Most patients have both peripheral eosinophilia ($>350/\mu\text{L}$) and lymphopenia ($<1000/\mu\text{L}$).²³⁹ The chronic syndrome is seen when the patient has been taking nitrofurantoin for 2 months to 5 years and is much less common than the acute syndrome. Pleural effusion develops in less than 10% of patients and is typically accompanied by pulmonary opacities.²³⁸

The diagnosis of nitrofurantoin pleuropulmonary reaction should be suspected in all patients with a pleural effusion who are taking nitrofurantoin. If the drug is discontinued, the patient usually improves clinically within 1 to 4 days. The chest radiograph becomes normal within a week with the acute syndrome, whereas the time course is much longer for the chronic syndrome.²³⁸

Dantrolene

Dantrolene sodium is a long-acting skeletal muscle relaxant with a chemical structure similar to that of nitrofurantoin. Its administration can lead to the development of pleural or pericardial disease.²⁴⁰ The pleural effusion is unilateral and develops 2 months to 12 years after the initial administra-

tion of dantrolene. Patients may be febrile and may have pleuritic chest pain. The pleural fluid is an eosinophilic exudate with a normal glucose level.²⁴⁰ When dantrolene is discontinued, the patient improves symptomatically within days, but it may take several months for the pleural effusion to resolve completely.

Methysergide

The administration of methysergide can lead to a pleuropulmonary disease similar to that seen with nitrofurantoin.²⁴¹ Symptoms consisting of chest pain, dyspnea, and fever develop 1 month to 3 years after methysergide therapy is initiated. The chest radiograph commonly shows bilateral localized pleural effusions and pleural thickening.²⁴¹ When methysergide is discontinued, the symptoms of the patients improve. However, in one series of 13 patients, severe pleural fibrosis persisted in the two patients who had continued to take the drug for the longest period (18 and 36 months) after the onset of the pleurisy.²⁴¹

Ergot Alkaloids

The administration of ergot alkaloid drugs such as bromocriptine, ergotamine, dihydroergotamine, nicergoline, pergolide, and dopergine in the long-term treatment of Parkinson disease can lead to pleuropulmonary changes.²³⁷ As of 1988, a total of 23 patients had been reported. All the patients were men, and the drug had been taken for 6 months to 4 years before symptoms developed. Two to 5% of patients receiving long-term ergot alkaloid therapy develop pleuropulmonary disease. The incidence of pleural disease is higher if the patient has previous exposure to asbestos.²⁴² The chest radiograph reveals unilateral or bilateral pleural thickening or effusion in most patients. Analysis of the pleural fluid reveals an exudate with predominantly lymphocytes and frequently eosinophils.²⁴³ The natural history of pleuropulmonary disease during ergot alkaloid therapy is unclear. The disease progresses only in some of the patients who continue taking the drug.²⁴³

Procarbazine

There have been two detailed case reports of pleuropulmonary reactions consisting of chills, cough, dyspnea, and bilateral pulmonary opacities with pleural effusion after treatment with procarbazine, a chemotherapeutic drug.⁶² In both cases, symptoms developed within hours after procarbazine therapy, recurred with rechallenge, and resolved with discontinuation.

Amiodarone

Amiodarone is an antiarrhythmic that may produce severe pulmonary toxicity. Pleural effusions are seen as a manifestation of amiodarone toxicity, but they are uncommon. Most cases have concomitant parenchymal involvement, but cases have been reported in which there is none.²³⁷ The pleural fluid is an exudate and may have predominantly lymphocytes, macrophages, or polymorphonuclear leukocytes.²³⁷

Interleukin-2

Recombinant IL-2 is sometimes used in the treatment of malignancies, especially melanoma or renal cell carcinoma. One of the primary side effects of IL-2 administration is the development of pulmonary opacities and pleural effusions

that are probably related to a generalized capillary leak syndrome.⁶² The incidence of pleural effusion after IL-2 administration is approximately 50%.²³⁷ The characteristics of the pleural fluid have not been described. After the IL-2 therapy is stopped, the effusions tend to disappear. However, in one study, 17% of patient still had a pleural effusion 4 weeks after cessation of therapy.²⁴⁴

Dasatinib

Dasatinib is an inhibitor of multiple tyrosine kinase inhibitors, used primarily for treating adults with chronic myeloid leukemia with resistance to prior therapy. Use of dasatinib is associated with a high incidence of pleural effusion. Qunitas-Cardama and associates²⁴⁵ reported that the effusion developed in 35% of 135 patients receiving the drug, and about half the effusions occupied more than 25% of the hemithorax. The effusions were bilateral in 80% of the patients. The effusions were mostly exudates. The effusions resolved when dasatinib was discontinued or when steroids were administered. The effusions are less common when dasatinib is administered once rather than twice per day. Interestingly, pleural effusion has been associated with a better clinical response to dasatinib.^{245a}

MISCELLANEOUS

Lung Transplantation

With lung transplantation, the lymphatics that normally drain the lung are severed. Accordingly, the fluid that normally leaves the lung via these lymphatics drains through the pleural space. Pleural complications such as hemothorax, empyema, and persistent air leak contribute substantially to the postoperative morbidity and mortality.^{245b} The incidence of pleural effusions at 3 months after transplant is about 30% to 60%.^{246,247} The incidence of effusion at 12 months is less than 10%.²⁴⁷ The effusions are characteristically a lymphocyte-predominant exudate with a benign course.²⁴⁶ However, patients who develop complications after lung transplantation are likely to develop pleural effusions. In one study, pleural effusions were seen with 74% of 19 episodes of acute rejection, 88% of 8 instances of chronic rejection, 55% of 11 episodes of infection, and 75% of 4 instances of lymphoproliferative disease.²⁴⁸ (More details about lung transplantation are provided in Chapter 106.)

Meigs Syndrome

Meigs and Cass²⁴⁹ originally described a syndrome characterized by ascites and pleural effusion in association with solid benign ovarian tumors. Subsequently, it has become apparent that a similar syndrome can be seen with benign cystic ovarian tumors, with benign tumors of the uterus (fibromyomas), and with low-grade ovarian malignant tumors without evidence of metastases.⁶² The ascites appears to result from the secretion of large amounts of fluid by the tumors. VEGF may play an important role in the pathogenesis of the ascites and pleural fluid because VEGF levels are high in both the ascites and pleural fluid.²⁵⁰ It is thought that the pleural effusion results from the ascitic fluid passing through defects in the diaphragm into the pleural space.

Patients with Meigs syndrome usually have a chronic illness characterized by weight loss, pleural effusion, ascites, and a pelvic mass. It is important to realize that not all patients with this constellation of symptoms have a disseminated malignancy. Approximately 70% of the effusions are right sided, and 20% are bilateral. The pleural fluid is usually an exudate with a relatively low white blood cell count ($<1000/\mu\text{L}$) and is occasionally bloody. The level of CA-125 in the pleural fluid may be elevated, and this should not be taken as an indication of malignancy.²⁵⁰

The diagnosis of Meigs syndrome should be considered in all women who have a pelvic mass, ascites, and a pleural effusion. If the cytology of the pleural fluid is negative in such patients, a diagnostic laparoscopy or an exploratory laparotomy should be performed to determine whether there are peritoneal metastases. The diagnosis is confirmed when the ascites and pleural fluid resolve after the primary neoplasm is removed, usually within the first 2 weeks after surgery.

Endometriosis

An occasional patient with severe endometriosis presents with massive ascites. In one review, 10 of 27 patients (37%) also had a pleural effusion.²⁵¹ The effusions are usually right sided but may be bilateral. The pleural fluid is a bloody or chocolate-colored exudate. The serum carcinoembryonic antigen level may be elevated, suggesting ovarian carcinoma. Hormonal therapy, including gonadotropin-releasing hormone agonists, may be attempted, but frequently it is ineffective and many patients require total abdominal hysterectomy plus bilateral salpingo-oophorectomy.²⁵¹

Ovarian Hyperstimulation Syndrome

This syndrome is a serious complication of ovulation induction. The dramatic clinical picture is characterized by massive ovarian enlargement with multiple cysts, hemoconcentration, and the third-space accumulation of fluid.²⁵⁰ The full-blown syndrome may be complicated by renal failure, hypovolemic shock, thromboembolic episodes, acute respiratory distress syndrome, and death. Although the pathophysiology of this syndrome is incompletely understood, it is likely that the increased capillary permeability is due to the increased VEGF production by the ovarian granulosa cells in response to the exogenous human chorionic gonadotropin.²⁵⁰

Patients with the syndrome present within 2 to 3 weeks of receiving the human chorionic gonadotropin. Patients typically present with abdominal pain and distention, non-productive cough, and dyspnea caused by the ascites, pleural effusion, or both. The pleural effusion is usually bilateral, and the pleural fluid is an exudate with predominantly neutrophils and a relatively low LDH level. The treatment of severe cases requires restoration of intravascular volume, correction of electrolyte abnormalities, and venous thromboembolism prophylaxis.²⁵⁰

Trapped Lung

Effusions that are remarkably stable over time, recur after thoracentesis, and are resistant to diagnosis may be due to an underlying trapped lung (Fig. 79-10). Following an earlier episode of inflammation, a fibrous peel may form over the visceral pleura and can prevent the underlying

Figure 79-10 Effusion with trapped lung. Frontal chest radiograph (A) shows a large right pleural effusion. On a subsequent radiograph (B), the effusion has been partially drained revealing the underlying lung with some visceral pleural thickening (arrow). The lung failed to re-expand despite negative intrapleural pressures. The intrapleural air entered the pleural space from the atmosphere along the drainage tract.

lung from expanding fully, thereby “trapping” the underlying lung. The resulting negative pleural pressure leads to the development of a chronic pleural effusion.^{252,253}

Patients with a chronic pleural effusion secondary to trapped lung are often asymptomatic but may have symptoms of dyspnea. Symptoms of acute pleural inflammation, such as pleuritic chest pain and fever, are distinctly uncommon, but the patient often gives a history of such events in the past. One characteristic of the pleural effusion secondary to trapped lung is that the amount of fluid is quite constant from one study to another. With trapped lung, the pleural fluid is often a borderline exudate; the ratio of pleural fluid to serum protein is about 0.5, and the ratio of pleural fluid LDH to serum LDH is about 0.6.

The diagnosis of pleural effusion secondary to trapped lung should be suspected in any patient with a stable, chronic pleural effusion, particularly if the patient has a history of uremia, thoracic radiation, or prior thoracic surgery.²⁵³ The thickened visceral pleura can be demonstrated if 200 to 400 mL of air is injected into the pleural space at the time of a thoracentesis. At some institutions, pleural manometry is used routinely during a therapeutic thoracentesis; if the pleural pressure falls rapidly (more than 14 to 15 cm H₂O per liter pleural fluid removed), air is allowed to enter the pleural space to return the pleural pressure to a more normal range (−5 cm H₂O) so that an air-contrast chest CT scan can be obtained to evaluate the visceral pleura.²⁵³

The definitive therapy for trapped lung is thoracotomy with decortication. However, this major surgery is indicated only in patients who are symptomatic from the trapped lung. If the patient is asymptomatic or minimally symptomatic, the patient can be observed if the clinical

picture, pleural fluid findings, and pleural pressure measurements are all compatible with the diagnosis of trapped lung.

Yellow Nail Syndrome

This syndrome consists of the triad of deformed yellow nails, lymphedema, and pleural effusions. The three entities may become manifest at widely disparate times and therefore are not all concurrently present in every patient. The basic abnormality responsible for this syndrome appears to be hypoplasia of the lymphatic vessels^{254,255} or a decrease in function of lymphatics.²⁵⁶ The onset of the condition is after puberty (mean age of onset 53 in one study,²⁵⁷ 61 in another²⁵⁸), may be acquired,²⁵⁷ and may resolve without treatment.²⁵⁷

Typically, the nails are pale yellow to greenish in color and are excessively curved from side to side (eFig. 79-10). They are also thickened and may show transverse ridging or onycholysis (separation of nail from bed). The pleural effusions are bilateral in about 50% of cases and can be massive. Once a pleural effusion has developed with this syndrome, it tends to persist and recur rapidly after thoracentesis.²⁵⁴ The pleural fluid is usually an exudate with predominantly lymphocytes.²⁵⁴ The pleural fluid LDH tends to be relatively low relative to the pleural fluid protein level.⁶²

The diagnosis is usually established by the presence of the triad of pleural effusion, lymphedema, and yellow nails. The diagnosis may be difficult to establish if the pleural effusion is the first manifestation of the syndrome. There is no specific treatment for the syndrome but, if the effusion is large and producing symptoms, the effusion can be treated with pleurodesis or decortication/pleurectomy.^{258a}

Pleural Effusions Due to Misplaced Catheters

Both internal jugular and subclavian vein catheterization can be complicated by misplacement of the catheter tip into the mediastinum or pleural space that results in a large unilateral (eFig. 79-11) or bilateral pleural effusion. The pleural fluid may have the characteristics of the intravenous fluid, or it may be bloody from laceration of the blood vessels.²⁵⁹ If the patient is receiving lipids through a central line, the fluid may look chylous.²⁶⁰ The diagnosis of a misplaced central venous catheter should be considered in all patients with such lines who rapidly develop pleural effusions, and the patients should be evaluated by diagnostic thoracentesis.

In the past several years, the development of soft, flexible, small-bore polyurethane feeding tubes has made nasogastric and nasoenteric feeding more practical and comfortable for patients. However, misplacement of these tubes can lead to serious pleural complications. Pneumothorax is the most common complication, but infusion of the enteral formula into the pleural space or the development of an empyema, or both, are also common.²⁶¹ These small flexible tubes are inserted with a stylet in place that enables easier advancement of the device. However, with the stylet in place, the tubing becomes stiff enough that it can perforate structures relatively easily. The risk is much greater if the patient has an endotracheal tube in place or is obtunded.²⁶¹ To prevent these complications, these tubes should be inserted only by experienced persons, and the tube should be immediately removed if the patient starts coughing. The tube should not be advanced if resistance is felt and, before feeding is initiated, the position of the tip of the tube should be confirmed radiographically.²⁶² If enteral solutions enter the pleural space, tube thoracostomy should be performed to remove the solution. In addition, the patient should be carefully observed for the development of an empyema.²⁶¹

Key Points

- Entry of normal fluid into the pleural space is normally slow, consistent with that found in other interstitial spaces of the body. Exit of fluid is mainly via parietal pleural lymphatics, which have a large reserve capacity and can normally accommodate increases in fluid formation without the development of an effusion.
- Pleural effusions develop when disease or combinations of diseases lead to an increase in fluid entry into the pleural space and a decrease in removal from the pleural space; both changes are likely necessary for formation of an effusion.
- Excess fluid elsewhere in the body can move to and enter the pleural space due to (1) subatmospheric pleural pressure (−5 to −30 cm H₂O), (2) the leaky

mesothelial layer, and (3) the high capacitance of the pleural space.

- Transudates usually result from systemic changes in hydrostatic and/or osmotic pressures that lead to collection of a relatively low protein and *lactate dehydrogenase* (LDH) fluid, with a pleural/serum protein ratio < 0.5 and pleural/serum LDH < 0.6 and LDH less than two-thirds the upper limit of normal (Light's criteria).
- Transudates with a *very* low protein concentration (<0.5 g/dL) come from entry of cerebrospinal fluid, urine, peritoneal dialysis fluid, or intravenous fluids into the pleural space.
- Exudates result from a multitude of inflammatory, infectious, or malignant diseases, leading to an effusion with a relatively high protein and/or LDH concentration.
- Most transudates arise from congestive heart failure. When the cause is unclear or when the protein and LDH ratios are not clearly transudative, as can happen after diuresis, the pleural fluid N-terminal probrain natriuretic peptide is a sensitive and specific marker for a cardiac etiology.
- Most exudates arise from pneumonia, malignancy, or pulmonary embolism.
- No diagnosis is ever established for approximately 20% of all exudative pleural effusions and many resolve spontaneously, leaving no residua. The degree to which a diagnosis is pursued by invasive procedures will depend on the (1) symptoms and the clinical course of the patient, (2) trend of the pleural fluid LDH level with time, and (3) eagerness of the patient for a diagnosis.

INTRODUCTION

Of the approximately 1 million cases of hospitalized pneumonia each year in the United States, around 60,000 will develop frank empyema. A further 25,000 are estimated to develop pleural infection for other reasons, including trauma and iatrogenic instrumentation.^{1,2} The annual estimated hospital cost for treating these cases is in excess of \$500 million.^{1,2} The morbidity and mortality rates in patients with pneumonia and associated pleural effusions are higher than for those in patients with pneumonia alone, with one study suggesting the increased relative risk for mortality was 3.4 times higher.³ There also appears to be a rising incidence of pleural infection internationally,⁴⁻⁶ but, despite continued advances in the management of this condition, morbidity and mortality have essentially remained static over the past decade.

HISTORICAL PERSPECTIVE

Infection of the pleural space is an ancient disease, with the earliest recorded description more than 5000 years ago⁷ and the first consistent description of its manifestations and treatment credited to the father of modern medicine, Hippocrates. Open thoracic drainage remained the standard treatment for pleural infection until the influenza pandemic of 1919; however, there was a 70% mortality rate associated with this treatment. In 1918 the U.S. Army Empyema Commission was formed to address the problem. They noted that dogs with empyema died more often if treated with early open drainage rather than delayed intervention, and the commission recommended using the closed-tube

drainage techniques described by Hewitt and Bulau.^{8,9} The commission's summary recommendations were: adequate pus drainage with a closed tube, avoidance of early open drainage, obliteration of the pleural space, and proper nutritional support. A landmark paper by Graham charted the successes seen during this time, with short-term mortality plummeting to 4%.¹⁰ These treatment principles, described almost 100 years ago, remain essentially unchanged to this day. The discovery of penicillin in the 1940s was a major advance that led to a further reduction in mortality. Surgical techniques beyond open drainage were developed in the late 19th century, with thoracoplasty described by Estlander¹¹ and Schede¹² and with decortication described by Fowler and Beck.¹³ It was only recently, however, that *video-assisted thoracic surgery* (VATS) was introduced and is being increasingly used today as the operation of choice in patients requiring surgery for their pleural infection.

INCIDENCE

There have been a number of recent reports from the United States, Canada, Europe, and Asia, all showing a dramatic increase in the incidence of pleural infection. This seems to be the case for both children and adults and, although most data are derived from developed-world populations, this pattern has been replicated around the globe.^{4,6,14-16} The incidence of pleural infection began to rise in the mid to late 1990s. This was captured by Grijalva and colleagues,⁶ who recently examined the trends in parapneumonic empyema in the United States over a 13-year period, demonstrating a doubling in the rates of empyema hospitalizations between

1996 and 2008, from 3.04 to 5.98 per 100,000. Similar results were demonstrated by a Canadian study, which also confirmed the significant disparity in empyema incidence between those 65 years of age and older (17 to 20 per 100,000) and those 19 years of age or younger (2 to 4 per 100,000).⁴

Mortality rates from empyema also seem to be on the rise. A study looking at the population of Utah showed a sixfold rise in mortality from the period 1950–1975 to the period 2000–2005.¹⁷ In a large series, inpatients were found to have a mortality up to 18% in the short term,¹⁸ with those in intensive care experiencing mortality as high as 41%.¹⁹ In a large multicenter trial from the United Kingdom, patients with an average age of 59 were shown to have a mortality rate 1 year after treatment for empyema between 8% and 20%.²⁰

The explanation for the increase in empyema incidence is not clear. With the introduction of the heptavalent pneumococcal conjugate vaccine in 2000, a reduction in pneumococcal empyema in children from serotypes covered by the vaccine may have led to an increase of cases caused by nonvaccine serotypes.²¹ This may account for an increase in adult infection with these serotypes. This, however, does not explain the increase in staphylococcal empyema seen in the series by Grijalva and associates.⁶

EPIDEMIOLOGY

Pleural infection is seen in patients of all ages but has a bimodal distribution, with a peak in childhood and a further rise in older adults. Men are affected twice as often as women,²² and this is illustrated in Figure 80-1, which shows the age and sex distribution of the large cohort of adult patients from the *Multicenter Intrapleural Sepsis Trial* (MIST) 1 study.²³ Pleural infection is also more common in those with diabetes, alcohol dependency, or drug addiction and those with rheumatoid arthritis.^{22,23} Poor dentition and aspiration have also been shown to be risk factors.¹⁸

The underlying etiology of pleural infection is varied, with most cases being of community origin. Although this

Figure 80-1 The age and sex distribution of pleural infection in adults in one large U.K. cohort. The disease is more common in males and the peak incidence in adults is in the 65- to 74-year-old age-range. (Data from Maskell NA, Davies CW, Nunn AJ, et al: U.K. controlled trial of intrapleural streptokinase for pleural infection. *N Engl J Med* 352:865–874, 2005.)

often results from a community-acquired pneumonia, a sizable proportion of cases show no evidence of consolidation on *computed tomography* (CT) imaging and are thought to have been acquired through hematologic spread or direct translocation from the oropharynx.²⁴ The next largest group are hospital-acquired pleural infections, which are often the result of prolonged hospital admissions for other initial reasons, or complications following surgery or invasive procedures. For example, pleural infections and other pleural complications are common after lung transplantation.^{24a} Other potential causes include direct (transdiaphragmatic) spread of abdominal sepsis, blunt or penetrating chest trauma, esophageal perforation, or rupture of a peripheral lung abscess into the pleural space.^{23,25,26}

PATHOGENESIS

The evolution of a pleural infection can be divided into three stages, which may overlap with each other. The first, *exudative* stage is characterized by the rapid outpouring of sterile pleural fluid into the pleural space. Some of this comes from the interstitial spaces of the lung and some from the parietal pleura because of increased permeability. The pleural fluid will have a low white blood cell count and *lactate dehydrogenase* (LDH) level, together with a normal glucose level and pH.^{27,28} At this stage chest tube drainage is rarely required, and antibiotics alone should suffice.

The second, *fibropurulent* stage evolves if bacteria invade the sterile exudative effusion. During this stage there is an accumulation of leukocytes, bacteria, and cell debris together with increased amounts of pleural fluid. Fibrin is then deposited over the visceral and parietal pleura, and there is a tendency at this stage for loculations to form within the pleural fluid, which may limit effective drainage of the effusion with a chest tube. The pleural fluid pH and glucose level will be lower, and the LDH level will rise, often dramatically.

The final *organization* stage is characterized by aggressive fibroblast growth over the pleural surfaces to form an inelastic membrane called the “pleural peel.” This is often extensive and reduces lung functionality considerably. The pleural fluid is often thick, consisting of pus and cellular debris.

Primary empyema instead arises by direct translocation from the oropharynx or by hematogenous spread. In this circumstance, bacteria invade the pleural space as the initial insult leading directly to the fibropurulent stage.

CLINICAL PRESENTATION

Although there have been some extremely unusual cases,⁴⁷ the classic presentation of prolonged pleural infection is difficult to separate from that of pneumonia, whereby patients suffer with dyspnea, cough, fever, malaise, and perhaps pleuritic chest pain.²⁹ In fact, a significant number of patients with pneumonia will go on to develop a parapneumonic effusion without a change in symptoms to offer clues to its existence. Furthermore, there is no symptomatic discriminator between patients with effusions determined to be uncomplicated or complicated.

An *uncomplicated* parapneumonic effusion is defined here as an effusion with a glucose level above 40 mg/dL, pH above 7.2, and negative Gram stain and culture without loculation on ultrasonography. A *complicated* parapneumonic effusion is either loculated on ultrasonography or has a glucose level below 40 mg/dL or a pH below 7.2. A high index of suspicion should be maintained for those patients who fail to improve within a few days of initiating antibiotic therapy³⁰ or who exhibit persistent fever or signs of sepsis, with further investigations following rapidly.³¹ With long-lasting infection, the course of patients with pleural infection can mimic the course of those with malignant processes, often with significant weight loss, sweats, and loss of appetite.

PLEURAL FLUID SAMPLING

Abnormal signs, symptoms, or blood test results in the context of a suggestive radiograph should lead to confirmation of the presence of an effusion and early sampling of the fluid. However, in a small retrospective series, Skouras and colleagues suggested that parapneumonic effusions less than 2 cm in thickness on chest CT scan can be treated with antibiotics without sampling because they are unlikely to become complicated or require intervention.³² Such patients would still require close monitoring and appropriate antibiotic therapy.

BIOCHEMISTRY

In cases where overt pus is revealed on initial aspiration, no further biochemical analysis is necessary, and chest tube placement is required. Microbiologic analysis is, however, still important in these cases.

Pleural fluid pH may be the best discriminator for a complicated pleural process during initial investigations, with many studies demonstrating better patient outcomes when drainage is instituted based on the early biochemical changes related to infection. In the meta-analysis by Heffner and coworkers,³³ the receiver operating characteristic for the diagnostic accuracy of pleural fluid pH showed that, if the pH was less than 7.2, a chest tube was likely to be necessary to resolve the pleural infection. A pH analysis (or glucose analysis) should therefore be performed in all cases where the diagnosis of pleural infection is being considered. The pH needs to be measured using a blood gas machine because pH strips and pH meters are not accurate enough to be of value.³⁴ Some institutions rely on the glucose concentration instead, finding it as useful a test and less prone to error.

Current guidelines therefore regard a pH of 7.2 as diagnostic of complexity, making this the definitive “cutoff” below which drainage should take place. It should be noted that fluid pH values may be appreciably altered by minor variations in sampling and processing techniques, which can therefore have significant effects on management strategy. In a study of pleural fluid pH, Rahman and associates reproduced several common scenarios that could result during testing. Even small amounts of residual heparin or local anesthetic in a sample syringe could dramatically

lower pH; residual air in the syringe could increase pH (if 1 mL of air was in the syringe with 2 mL of fluid, the pH rose by an average of 0.08). These errors represented a clinically significant change in over two thirds of patients.³⁵

As mentioned earlier, when pH measurements are not easily obtainable, a glucose level can be useful.³³ Samples should be collected in a blood glucose tube and sent to the laboratory, with a value of less than 2.2 mmol/L (40 mg/dL) indicating the need for chest tube drainage.^{33,35} It should be noted that pH and glucose level can also be low in malignant pleural effusions, rheumatoid pleural effusions, and pleural effusions secondary to esophageal rupture; therefore their value for guiding chest tube drainage should be restricted to the setting of parapneumonic effusions.

LDH measurements tend to be high in all cases of complicated parapneumonic effusions and empyema. LDH tends to rise rapidly as the pleural infection progresses through the fibropurulent and organizing stages of the disease. When a patient is being treated with antibiotics alone, a rising LDH on repeated thoracentesis may indicate that an effusion is not responding and chest tube drainage should be considered.

MICROBIOLOGY

The bacteriologic features of culture-positive pleural fluid have changed since the introduction of antibiotics. In the preantibiotic era, the commonest pathogens were *Streptococcus pneumoniae* or *Streptococcus haemolyticus*.³⁶ After this period, between 1955 and 1965, *Staphylococcus aureus* was the commonest causative organism, with the major shift in the frequency and type of causative organisms attributable to the introduction of antibiotics. There also appear to be global and regional differences in the frequencies and range of the causative organisms.

In a study of patients with pleural infection,³⁷ standard culture methods were combined with nucleic acid amplification to discern causative organisms, attaining a 74% overall identification rate. Cloning techniques were also applied to a small number of cases (3%), limited by cost. Nucleic acid amplification identified an organism in 38% of the culture-negative samples, with the same organism found by both culture and nucleic acid amplification (or cloning) in 35% of cases.

In this cohort of mostly community-acquired pleural infections (85%), the *Streptococcus anginosus* group (formerly *Streptococcus milleri* group) was the predominant species of bacteria. These and other gram-positive aerobes were implicated in 65% of cases, confirming the inherent differences in etiology of empyema compared to pneumonia. Other organisms included staphylococci (11%), gram-negative aerobes such as *Escherichia coli* (9%), and anaerobes (20%). Polymicrobial samples were identified in 20% of cases, but this may well underestimate the true incidence, as suggested by the results using cloning in the study and the fact that anaerobes, which have been identified in up to three quarters of cases of community-acquired pleural infection in other series, may have been underrepresented in this series.³⁸

Hospital-acquired pleural infections made up only 15% of this cohort overall but were quite different from the

Table 80-1 Summary of 2175 Culture-Positive Cases of Pleural Infection (including Both Hospital-Acquired and Community-Acquired Cases) in English Language Literature between 1996 and 2012

Organism—Aerobes (Gram-Positive)	Percent	Organism—Aerobes (Gram-Negative)	Percent	Anaerobes	Percent
<i>Streptococcus pneumoniae</i>	32	<i>Escherichia coli</i>	3	<i>Fusobacterium</i>	2
<i>Streptococcus milleri</i> group	10	<i>Klebsiella</i> spp.	3	<i>Bacteroides</i>	2
Other <i>Streptococcus</i> spp.	10	<i>Haemophilus influenzae</i>	1	<i>Peptostreptococcus</i>	6
<i>Staphylococcus aureus</i>	10	Other coliform spp.	2	<i>Prevotella</i>	1
<i>Streptococcus pyogenes</i>	2	<i>Proteus</i>	1	Mixed anaerobes	1
Methicillin-resistant <i>S. aureus</i>	2	<i>Enterobacter</i> spp.	2	Other	6
<i>Enterococcus</i> spp.	1	<i>Pseudomonas aeruginosa</i>	3		
Total	67		15		18

community-acquired pleural infections. Most (58%) cases were attributed to gram-negative organisms or staphylococci, with over 70% of the latter due to methicillin-resistant *S. aureus*.³⁷ A similar gram-negative predominance has been found among patients in the intensive care setting.¹⁹ The bacteriology of hospital-acquired pleural infection is therefore very different from that of community-acquired pleural infections and requires different empirical antibiotics at presentation. Table 80-1 summarizes the frequency of over 2000 culture-positive cases reported in the English literature between 1996 and 2012.

The use of blood culture bottles for culturing pleural fluid can increase yield; Menzies and colleagues³⁹ provided the first comparative, prospective evidence of increased microbiologic diagnostic yield in pleural infection using the BACTEC blood culture bottle system (Becton, Dickinson U.K.). Addition of blood culture bottle-inoculated pleural fluid at the bedside to standard pleural fluid culture increased microbiologic diagnostic yield by 21%, and, in a small proportion of cases (4%) where the standard culture was positive, use of the blood culture bottles suggested the presence of additional organisms that would alter antibiotic management. These findings are further supported by the lack of false-positive culture results from noninfected control samples. The standard cultures were positive in 29% of cases in which the pleural fluid cultured in blood culture bottle cultures were negative, suggesting potential organism preference for certain growth media. This study demonstrates a significant increase in diagnostic yield using a widely available and relatively inexpensive technique, suggesting that inoculation of pleural fluid into blood culture bottles should be added to standard pleural fluid culture routinely.

ANTIBIOTIC SELECTION AND DURATION

The initial empirical antibiotic selection at presentation should be based on whether the pleural infection is community acquired or hospital acquired. Hospital-acquired pleural infection has a different range of causative organisms and a considerably higher mortality (Fig. 80-2).

Because anaerobic bacteria are commonly seen in this setting and often fail to grow in culture, they should be

Figure 80-2 Survival following pleural empyema. Kaplan-Meier survival curves comparing community-acquired and hospital-acquired pleural infection in the Multicenter Intrapleural Sepsis Trial cohort, showing the significantly higher mortality rates in those with hospital-acquired pleural infection. (From Maskell NA, Batt S, Hedley EL, et al: The bacteriology of pleural infection by genetic and standard methods and its mortality significance. *Am J Respir Crit Care Med* 174:817–823, 2006.)

covered empirically in all cases of presumed pleural infection. Liaison with local microbiologists is invaluable in deciding the best combination of antibiotics to use, because resistance patterns vary significantly from one geographic region to the next.

There are no robust studies looking at the optimal duration of antibiotics for pleural infection. In our experience, if a patient is ill enough to require hospitalization, then intravenous antibiotics are usually indicated. When converted to an oral equivalent, perhaps before discharge, a further 1 to 3 weeks of antibiotics is commonly needed. The length of the antibiotic course is governed by the inflammatory markers (*C-reactive protein* [CRP]) and any ongoing, often mild fever, rather than by the radiologic appearance, which often lags behind clinical improvement.

The potential role of intrapleural antibiotics is not often considered and randomized, controlled trial data are lacking. Because most intravenous antibiotics penetrate into the pleural space in suitable concentrations, there is no current role for intrapleural antibiotic use in this setting. However, it should be noted that aminoglycosides do not penetrate the pleural space well and should be avoided.

NUTRITION

Patients with pleural infection, particularly those with empyema who have had a delayed presentation, suffer the protracted catabolic consequences of chronic infection. A low albumin level has been shown to be a marker of poor outcome in one large published series.⁴⁰ Addressing the patient's nutritional status at presentation is often overlooked and should be an early priority alongside tube drainage and the prescribing of suitable antibiotics. Early nutritional assessment should be seen as mandatory.

EARLY RISK STRATIFICATION

A reliable and sensitive clinical prediction model of poor outcome in pleural infection would enable clinicians to triage patients according to risk and to select the more aggressive and expensive therapies for patients who may otherwise have the poorest outcomes. To date, there are no robust validated methods for identifying high-risk patients at presentation with pleural infection. Selection for surgery has previously been based on duration of symptoms, pleural fluid purulence, size of infected pleural fluid collection, and the degree of parietal pleural thickening on imaging. In a cohort study of 85 sequential patients, clinical care was based on structured treatment guidelines to assess whether the generally accepted baseline predictors reliably identified patients at high risk. Only pleural fluid purulence had predictive power for a poor outcome, and this was insufficiently sensitive and specific to be of clinical value.⁴¹ In a second study, this finding was confirmed and predictors of residual pleural thickening were identified, although thickening was uncommon and not associated with clinical disability.⁴²

Although there are likely to be complex interactions between genetic and environmental factors that contribute to the development of pleural infection,²¹ these have not yet been determined. There are, however, certain patient risk factors, particularly chronic alcohol excess and intravenous drug use, which likely increase the risk because of aspiration of gastric contents. In addition to these, Chalmers and colleagues⁴³ described four other independent risk factors that seem to predict the development of pleural infection: serum albumin level below 30 g/L, serum CRP greater than 100 mg/L, platelet count above $400 \times 10^9/L$, and serum sodium level below 130 mmol/L. This study noted that none of the routinely employed pneumonia or sepsis scores were adequate in determining this outcome and suggested a score based on these six factors, although this still requires validation. Interestingly, patients with chronic obstructive pulmonary disease were found to be at lower risk for developing pleural infection, perhaps due to a background level of generalized inflammation causing an attenuated response to a pleural bacterial challenge.⁴⁴

For patients with confirmed pleural infection, those at greatest risk for poor outcome may be identifiable.⁴⁵ For the patients recruited to the U.K. MIST1 trial, an outcome score was developed and subsequently validated using a second cohort from the MIST2 trial. Of the 32 baseline characteristics analyzed, 5 presenting factors (age, serum urea level, serum albumin level, fluid purulence, and likely origin of

infection) could predict the eventual outcome, with patients divided into low-, medium-, or high-risk groups. Patients in the lowest risk group were found to have a mortality of less than 5% at 3 months, whereas those in the highest were found to have a mortality approaching 50% over the same time period. The main potential advantage of this stratification system is in allowing physicians to institute fibrinolytics or surgery earlier in the clinical presentation when they are perhaps more likely to be successful.

IMAGING TECHNIQUES FOR PLEURAL INFECTION

Radiologic tests are vital in the initial diagnosis and management of pleural infection. Chest radiography, CT, and ultrasonography are all useful tools in the management of patients with pleural infection.

RADIOLOGY

The presence of fever, pleuritic pain, and pleural effusion should always alert the physician to the possibility of pleural infection. Pleural fluid loculation can result in a D-shaped subpleural opacity (Fig. 80-3 and eFig. 80-1A) on chest radiography, which could be misinterpreted as a lung mass if one is not aware of this common appearance. In ventilated patients in the supine position, free fluid may track posteriorly and cause haziness of the hemithorax on the chest radiograph.

Thoracic ultrasonography (see eFig. 80-1) is advisable in all cases of suspected pleural infection because it can provide important information and it allows accurate chest tube placement into the most appropriate part of the pleural collection. Use of ultrasonography has also been shown to reduce iatrogenic injury.⁴⁶ Ultrasonography is also more accurate than CT imaging in detecting loculations and

Figure 80-3 Pleural empyema. Frontal chest radiograph showing the D-shaped opacity, suggesting an extraparenchymal process, which is commonly seen in cases of pleural infection.

septations and can detect the presence of small quantities of pleural fluid not visible on chest radiography.

Chest CT (see [eFig. 80-1H–K](#)), particularly contrast-enhanced chest CT ([eFig. 80-2](#)), is not necessary in all patients with pleural infection and should be reserved for those with persistent collections despite attempted chest tube drainage, those who may have a suspected proximal obstructing lesion, and those in whom surgery is being considered. It will provide detailed information about fluid loculation ([Video 80-1](#)), identify chest tube position, and differentiate between empyema and lung abscesses (see [eFig. 33-7B–E](#)) when there is diagnostic uncertainty ([Fig. 80-4](#) and [Table 80-2](#)).

Magnetic resonance imaging is usually reserved for those patients who are unable to undergo CT imaging or for persons at high risk from irradiation. It is very good at visualizing septations and loculations within the pleural fluid ([Fig. 80-5](#)).

BRONCHOSCOPY

Practitioners should be aware that a proximal obstructing lesion may be the cause of an empyema. Although uncommon (less than 4% in one large series), it should be considered in patients with a suggestive plain chest radiograph, especially one in which the mediastinum is shifted toward the side of the effusion, or in those failing to respond to

simple first-line management. A bronchoscopy and chest CT would be the investigations of choice if a bronchial obstruction is suspected. There is no role for routine bronchoscopy in all patients with pleural infection.

When an empyema is discovered distal to an obstructed bronchus, the underlying cause is usually malignancy. Once histologic confirmation has been obtained, relief of the obstruction with radiation therapy, laser resection, or stent insertion might allow the empyema to be treated effectively. Where this is not possible, prolonged oral antibiotics may be useful to prevent ongoing sepsis.

Table 80-2 Key Differences between the Radiographic Appearance of Pleural Infection and Lung Abscesses

Empyema	Lung Abscess
Lenticular shape	Rounded
Surrounding lung often compressed	Boundary between lung and fluid indistinct
Margins of collection create obtuse angles with chest wall	Makes contact with chest wall at acute angle
Thick smooth wall	Thick irregular wall
No vessels close by	Vessels seen passing through or near collection

Figure 80-5 Magnetic resonance imaging (MRI) of pleural empyema. **A**, Contrast-enhanced chest CT revealing a complex, large left pleural fluid collection secondary to pleural infection. **B**, T2-weighted MRI in the same patient revealing the presence of multiple septations and loculations.

TUBE SIZE

Over the past decade there has been a shift away from large-bore catheters to small-bore chest tubes inserted by the Seldinger technique. This change in practice is not so much the result of large, well-conducted, randomized controlled trials but more to do with the relative ease of the technique and the benefits of the smaller drains, which cause the patient less pain during insertion and while in situ.⁴⁷

For cases of pleural infection, we recommend initial placement of a small-bore (12-French) chest tube under ultrasonographic guidance and then management with regular saline flushes to ensure that it does not become occluded. Guidelines recommend the instillation of 30 mL saline every 6 hours via a three-way stopcock. If this fails to drain the effusion effectively, a large-bore drain may occasionally be necessary. It is more common for tubes to be replaced not because of obstruction but because they have become dislodged or fall out as a result of failure to secure the chest tube correctly.

Although there are no randomized data comparing large-bore with small-bore chest tubes for pleural infection, one study reviewed the 405 patients who participated in the MIST trial. As part of the study, data were collected about the size of chest tube used. No difference between small- and large-bore tubes was found in the frequency with which patients either died or required thoracic surgery. However, those with larger chest tubes reported significantly more pain both at the time of insertion and while the drain remained in situ.⁴⁸

In another study of 103 patients with pleural infection, the small-bore chest tubes provided definitive treatment in 78% of cases,⁴⁹ similar to the success rates of two other series in which large-bore chest tubes were used.^{50,51} It should be noted that, in this study, radiologists guided tube placement, which almost certainly helped the result. With this in mind, we recommend that chest tubes should be placed under ultrasonographic guidance in the largest locule in a dependent part of the pleural effusion.

FIBRINOLYTIC THERAPY

The use of fibrinolytic agents to disrupt fibrinous pleural septations was first described by Tillett and Sherry in 1949,⁵² who used partially purified streptococcal fibrinolysin that contained both streptokinase and streptodornase (a DNase) to drain infected postoperative hemothoraces. It was associated with immunologic side effects and did not become routine practice.

Streptokinase is a proteolytic enzyme derived from a bacterial protein of group C β -hemolytic streptococci. It forms a complex with plasminogen that then converts additional circulating plasminogen to plasmin. Plasmin lyses fresh fibrin clot and digests prothrombin and fibrinogen. Because it is derived from a bacterial source, it is antigenic, unlike urokinase.

In a series of 24 patients, Davies and coworkers⁵³ began to allay fears regarding intrapleural thrombolysis, which was found to be safe and also led to improvements in clinical outcomes. Other studies tended to focus more on the use of

urokinase in loculated effusions, with benefits being demonstrated in terms of a reduction in treatment failure (as judged by surgical referral or death), reduced length of hospital stay, and better surgical outcomes.⁵⁴⁻⁵⁶ However, these studies were often small trials or case series, which limited their ability to be generalized.

The 2005 MIST1 trial²³ recruited 454 pleural infection patients from the United Kingdom to receive either intrapleural streptokinase or placebo. Entry criteria reflected real-world practice with a strong reliance on local physician diagnosis, antibiotic choice, chest tube use, and surgical referral. The trial was unable to show any significant benefit from the use of streptokinase in either surgical referral or death. There was also no improvement in the length of stay or in any signal in any subgroup analysis. However, a Cochrane review found that intrapleural fibrinolytics conferred benefit both in reduced treatment failure and reduced need for surgical intervention in pleural infection, but not reduced mortality.⁵⁷ The choice of streptokinase as the primary lytic may have contributed to these results, because its mechanism of action relies upon using a proportion of the intrapleural plasminogen to form an active complex before the rest can be converted to plasmin.⁵⁸ Nonetheless, the 2010 British Thoracic Society guidelines advised that intrapleural fibrinolytics should not be used routinely, but might be considered in select cases.⁵⁹

Following this, in the blinded, 2-by-2 factorial MIST2 trial,²⁰ 210 patients with pleural infection were randomly assigned to receive one of four study treatments for 3 days: intrapleural *tissue plasminogen activator* (t-PA) and DNase, t-PA and placebo, DNase and placebo, or double placebo. The primary outcome was the change in pleural opacity, measured as the percentage of the hemithorax occupied by effusion on chest radiography on day 7 as compared with day 1. The mean (\pm SD) change in pleural opacity was significantly greater in the t-PA–DNase group than in the double placebo group ($-29.5\% \pm 23.3\%$ versus $-17.2\% \pm 19.6\%$; difference, -7.9%); the change observed with t-PA alone and with DNase alone ($-17.2\% \pm 24.3\%$ and $-14.7\% \pm 16.4\%$, respectively) was not significantly different from that observed with placebo. The frequency of surgical referral at 3 months was lower in the t-PA–DNase group than in the double placebo group (2 of 48 patients [4%] versus 8 of 51 patients [16%]; the odds ratio for surgical referral, 0.17, and was greater in the DNase group (18 of 46 patients [39%]) than in the placebo group (odds ratio, 3.56). Combined t-PA–DNase therapy was associated with a reduction in the hospital stay as compared with double placebo (difference, -6.7 days); the hospital stay with either agent alone was not significantly different from that with placebo.

The authors concluded that intrapleural t-PA–DNase therapy improved fluid drainage in patients with pleural infection and reduced the frequency of surgical referral and the duration of the hospital stay. Treatment with DNase alone or t-PA alone was ineffective; indeed, DNase monotherapy was associated with an increase in surgical referrals by a factor of 3. Reduction in the infected pleural fluid collection was roughly doubled with the use of the combination therapy (with clearing of approximately 30% of the ipsilateral hemithorax volume and about a 60%

reduction in the baseline pleural collection). This treatment was not associated with an excess of adverse events. In a report from eight centers, the use of tPA/DNase also showed benefit, although with some pain and bleeding, in those who did not respond to antibiotics and thoracostomy drainage.^{59a} In summary, this approach looks promising, although a larger trial is needed to confirm safety and guide physicians on which patient groups are likely to gain the most benefit.

MONITORING RESPONSE TO MEDICAL MANAGEMENT

Identifying patients who are not responding to medical management can be a challenging task. Improvements in the imaging appearance often lag behind clinical improvement and therefore, in our opinion, are not a good indicator of the need for further intervention. The best markers of response to medical management include a falling CRP (halving in value and ideally falling to below 100 mg/L), the settling of a spiking temperature, and clinical signs associated with resolution of sepsis. If these markers are all improving, then further interventions with additional chest tubes or surgery rarely becomes necessary.

When patients look as if they have avoided surgery by the narrowest of margins, prolonged oral antibiotics (for 4 to 6 weeks) and close follow-up as outpatients with monitoring of the chest radiograph and CRP is advised.

SURGICAL OPTIONS

Patients are usually referred for surgical intervention after initial medical treatment failed or if they presented late with highly organized empyemas that demonstrate significant pleural thickening and loculation. Practice varies, with some centers having an extremely low threshold for early surgery.⁶⁰ The point at which medical management is deemed to have “failed” is necessarily ill defined, but one important indicator would be signs of ongoing sepsis despite attempted chest tube drainage and adequate antibiotic therapy. Another important consideration is the risk for long-term respiratory embarrassment without the removal of the fibrin and loculated fluid.

Modern surgical options are varied and may be tailored to the individual. VATS typically requires general anesthetic and single-lung ventilation but can be performed under local anesthetic in patients deemed too high risk for a general anesthetic (Fig. 80-6 and Video 80-2). Although originally used for thorough pleural débridement,⁶¹ VATS can now be used to perform decortication in particularly advanced or chronic empyema, although this latter situation may reduce the chance of successful outcome.⁶² Despite this, overall success rates for VATS, measured by resolution of sepsis and clinical stability, exceed 85%.

Open decortication for empyema was formerly a mainstay of treatment, but its role is likely to become increasingly marginalized as VATS surgery becomes commonplace.⁶³ It is therefore now used when less invasive approaches have failed. Decortication following thoracotomy allows com-

Figure 80-6 Empyema in a 26-year-old woman at the time of video-assisted thoracic surgery (see Video 80-2).

plete mobilization of the lung, which is particularly useful in cases of trapped lung.⁶⁴ A study from 1996 described a mortality of about 3% for this operation.⁶⁵

When managing patients with pleural infection in the acute stages, decortication should only be considered for the control of pleural infection. Decortication should not be performed just to remove thickened pleura because such thickening usually resolves spontaneously over the subsequent 4 to 6 months.

For patients who have recurrent or particularly complex empyema, small prosthetic devices may be inserted between the ribs to maintain a drainage route. The more permanent way to achieve this effect is to perform an open-window drainage. This involves the resection of two or three ribs to create a direct opening to the thoracic cavity, which affords the opportunity to pack the pleural space.⁶⁶ The advantage of this open flap (Eloesser flap, eFig. 80-3) is that it creates a skin-lined fistula that provides drainage without tubes. Should methods such as these fail, a thoracomyoplasty may become necessary, whereby a large muscle is used to pack the thoracic cavity. This is usually reserved for patients with bronchopleural fistulas (see eFig. 80-3B), trapped lung, or postoperative empyema.⁶⁴

A more conservative approach, which may be applied in highly selected patients who have high risks for surgery, is the insertion of an indwelling pleural catheter together with long-term oral antibiotic therapy.⁶⁷ In our experience, this approach can occasionally be extremely useful and would certainly warrant further research.

SUMMARY

The worldwide incidence of pleural infection due to bacteria is rising, with a changing spectrum of causative organisms and underlying etiology. Early recognition and instigation of simple therapies such as antibiotics, nutritional supplements, and chest drainage remains the cornerstone of good management. For patients who have incomplete drainage, intrapleural fibrinolytic therapy with t-PA combined with DNase appears to offer a good alternative to surgical intervention. However, further trials are needed in this area to ascertain its place in the treatment algorithm. Meanwhile, minimally invasive surgical intervention such as VATS is being practiced more widely, and

frailer patients are increasingly being offered definitive surgical intervention, under local anesthetic if necessary.

TUBERCULOUS PLEURITIS

In many parts of the world, the most common cause of an exudative pleural effusion is *tuberculosis* (TB). However, in the United States, tuberculous pleuritis is relatively uncommon, with only 7549 cases reported in the 10 years from 1993 to 2003; the number of cases of pleural TB constituted 3.6% of the total number of cases of TB seen over this period.⁶⁸ In some African countries, the incidence of pleural involvement in TB appears to be much higher because the percentage of patients with TB who have a pleural effusion exceeds 30%.⁶⁹ The effect of *human immunodeficiency virus* (HIV) on the incidence of tuberculous pleurisy is still uncertain; in some studies HIV appears to increase the incidence, and in others it does not.⁶⁹ Some authors suggest that pleural TB in those with HIV has a different pathogenesis compared to the disease in those without HIV,⁷⁰ but the confusion may in part be due to the state of immunocompromise. The prevalence of tuberculous pleurisy is also higher in patients with CD4 counts above 200 cells/ μ L than in those with CD4 counts below 200 cells/ μ L,⁷¹ in keeping with the understanding of the role of delayed hypersensitivity in the development of the effusion.

A pleural effusion as a manifestation of TB has been likened to a primary chancre as a manifestation of syphilis. Both are self-limited and of little immediate concern, but both may lead to serious disease many years later. Most instances of pleural effusion secondary to TB resolve spontaneously; however, if patients are not treated with antituberculous therapy, they have about a 50% likelihood of developing active TB in the subsequent 5 years.⁷⁷

PATHOGENESIS

A tuberculous pleural effusion can either be a sequel to a primary infection acquired 3 to 6 months previously or represent reactivation TB. A molecular epidemiologic study confirmed that tuberculous pleurisy is usually an early manifestation of TB infection.⁷² Delayed hypersensitivity appears to play a large role in the pathogenesis of tuberculous pleuritis. In sensitized animals, the intrapleural injection of tuberculin protein results in the rapid appearance of an exudative pleural effusion.⁷³ When the animals are given antilymphocyte serum, the development of the effusion is suppressed. The observation that pleural fluid cultures are negative in approximately 80% of patients with tuberculous pleuritis supports the contention that delayed hypersensitivity also plays a large role in the development of tuberculous pleural effusions in humans. Although delayed hypersensitivity to tuberculin protein is believed to be primarily responsible for tuberculous pleuritis, about one third of patients with tuberculous pleuritis have a negative tuberculin skin test result when first evaluated. The negative skin test is thought to be due to the sequestration of circulating purified protein derivative-reactive lymphocytes in the pleural space or suppressor cells, either adherent monocytes or Fc-bearing lymphocytes, that are found in the blood but not in the pleural space.⁷³

CLINICAL MANIFESTATIONS

Tuberculous pleuritis presents as an acute illness in about two thirds of cases and as a chronic illness in the remaining one third. The acute illness is marked by cough and chest pain in about 75% of patients and often mimics a bacterial pneumonia with parapneumonic effusion (eFig. 80-4). The chronic form is characterized by low-grade fever, weakness, and weight loss.

Effusions secondary to tuberculous pleuritis can present in a similar fashion as malignant effusions, being almost always unilateral, and usually small to moderate in size, although they may be large (eFig. 80-5), to the point of occupying the entire hemithorax. Up to 86% of patients will have coexisting parenchymal disease (eFig. 80-6; see eFigs. 80-4 and 80-5). In such patients the pleural effusion is almost always on the side of the parenchymal opacity and invariably indicates active parenchymal disease. It is likely that, even in cases with no radiographic evidence of parenchymal involvement, the effusion is associated with a subpleural focus of infection. Evidence to support this contention is provided by a study in which the yield of sputum induction for *Mycobacterium tuberculosis* was as high in patients with no radiographic evidence of parenchymal involvement (55%) as in those with evidence of parenchymal disease (45%).⁷⁴

PLEURAL FLUID

The pleural fluid from patients with tuberculous pleuritis is an exudate that usually contains predominantly small lymphocytes, although, in a series from 2012, 17% of confirmed cases were found to have less than 50% lymphocytes in pleural fluid.⁷⁵ In around 11% of cases, the fluid will have a polymorphonuclear leukocyte predominance, with this more likely to be the pattern in the earlier stages of the disease.⁷⁶ The pleural fluid glucose level is usually similar to that of serum, but it can also be reduced. A pleural fluid protein level above 5.0 g/dL is suggestive of tuberculous pleuritis, perhaps due to the intense inflammation and leakiness of the pleural capillaries.

DIAGNOSIS

The possibility of tuberculous pleuritis should be considered in every patient with an undiagnosed exudative pleural effusion, even though only a small percentage of such effusions are due to TB in the United States.⁷⁷ For the past 40 years, the most common way to establish the diagnosis of tuberculous pleuritis has been with biopsy of the pleura, and this remains the “gold standard” test. However, in recent years, pleural fluid tests have been developed that may be useful in establishing or excluding the diagnosis of tuberculous pleuritis.⁷⁷ Those that have found the most utility, especially in combination, are (1) the level of *adenosine deaminase* (ADA) in the pleural fluid, (2) the level of interferon- γ in the pleural fluid, and (3) polymerase chain reaction for mycobacterial DNA. All patients should have at least one of these tests performed on their pleural fluid. There was initial hope that interferon- γ release assays might be of diagnostic benefit when applied to pleural fluid,^{78,79} but this appears not to be the case.^{80,81} Other markers that

have been investigated include CRP,⁸² ADA2,⁸³ and tumor necrosis factor- α .⁸⁴

All patients with an undiagnosed exudative pleural effusion should undergo mycobacterial cultures of their pleural fluid. It has also been suggested that enhanced culture methods such as the Microscopic Observation Drug Susceptibility assay may have a role in diagnosing pleural TB without the need for biopsy.⁸⁵ An induced sputum sample should also be sent for smear and culture, because it will be positive in approximately 50% of patients.⁷⁴ If the culture of the fluid or sputum is positive, standard treatment for TB should be initiated. If culture is negative but one of the other tests is positive, the patient should also be treated for TB unless the patient has a disease that is known to be associated with a positive result, or if the index of suspicion is low for another reason. In areas with a high likelihood of resistant TB, one may be more inclined to obtain pleural tissue for cultures via needle biopsy of the pleura or thoracoscopy, if available. Thoracoscopic biopsies remain the ideal way of obtaining tissue but, if this resource is not available, then traditional blind pleural biopsy remains an important diagnostic modality,⁸⁶ especially when used in combination with ADA and differential cell count.⁸⁷ Blind pleural biopsy with an Abrams needle may be preferable to other forms of blind biopsy when ultrasonographic guidance is used.⁸⁸ If the patient does not respond to therapy, then further investigations for alternative causes are warranted.

TREATMENT

Patients with tuberculous pleuritis should be treated with antituberculous medications in the same treatment regimens as patients with pulmonary TB. With treatment, patients generally become afebrile within about 2 weeks, and the pleural effusion resolves within 6 weeks. On occasion the pleural effusion worsens after antituberculous therapy is initiated⁸⁹ or a pleural effusion develops while patients are being treated for parenchymal TB.⁹⁰ In these situations, the possibility of a wrong diagnosis must be considered, but paradoxical worsening can be seen with the correct diagnosis and appropriate antituberculous medications.^{89,90} Mild degrees of residual pleural fibrosis are present a year after therapy is begun in about 50% of patients. Some authors have used fibrinolytics during drainage of tuberculous effusions with good long-term improvement in the residual fibrosis.⁹¹ Despite this, the presence of fibrosis is not necessarily related to the initial pleural fluid findings and may be of limited clinical significance.

The role of systemic corticosteroids in the treatment of tuberculous pleuritis remains controversial. According to a literature review, there were insufficient data to support evidence-based recommendations regarding the use of adjunctive corticosteroids in persons with tuberculous pleurisy.⁹² Use of corticosteroids may be considered for those who are markedly symptomatic, but only after the institution of appropriate antituberculosis therapy. However, evidence suggests that their use in HIV-infected patients with TB pleuritis should be avoided due to the increased risk for Kaposi sarcoma.⁹³ Therapeutic thoracentesis is indicated if the patient has a moderate-sized or larger pleural effusion producing symptoms. Otherwise, complete

drainage of the pleural space does not appear to have a significant effect on the long-term outcome.⁹⁴

ACTINOMYCOSIS

More than 50% of patients with thoracic actinomycosis have pleural involvement.⁹⁵ In one series of 15 patients, 6 had pleural effusion and an additional 6 had marked pleural thickening.⁹⁵ The characteristic chest radiographic finding is a localized lung lesion extending to the chest wall with pleural thickening or effusion. The pleural fluid with actinomycosis may be either frank pus with predominantly polymorphonuclear leukocytes or serous fluid with predominantly lymphocytes.

The diagnosis of actinomycosis should be considered when a chronic infiltrative pulmonary lesion extends to adjacent lobes through intralobar fissures. The presence of chest wall abscesses or draining sinus tracts suggests the diagnosis, as do bone changes consisting of periosteal proliferation or bone destruction (see eFig. 33-23B). The definitive diagnosis is established with the demonstration of *Actinomyces israelii* by anaerobic cultures. Patients with pleural actinomycosis should be treated with high doses of penicillin or another suitable antimicrobial for prolonged periods. The management of the pleural effusion is similar to that for patients with any other bacterial pneumonia.

NOCARDIOSIS

Pleural effusions develop in roughly 50% of patients with pulmonary nocardiosis.⁹⁵ Patients with pleural effusion secondary to nocardiosis almost always have an associated parenchymal opacity (eFig. 80-7). The pleural fluid can range from serous fluid to frank pus, and pleural fluid cultures may or may not be positive. Because most patients who develop nocardiosis are immunosuppressed,⁹⁶ this diagnosis should be considered in the immunosuppressed patient with a parenchymal opacity and a pleural effusion. The diagnosis is usually established with aerobic cultures, although polymerase chain reaction has been successfully used in some cases.⁹⁷ Cultures should be observed for at least 2 weeks because *Nocardia asteroides* is a slow-growing organism. Patients with pleural nocardiosis should be treated with sulfonamides or suitable alternative antimicrobials, and the pleural effusion should be managed as any pleural effusion complicating a pneumonia.

FUNGAL INFECTIONS

Fungal infections of the lungs are discussed in Chapters 37 and 38. This section considers the pleural complications of aspergillosis, blastomycosis, coccidioidomycosis, cryptococcosis, and histoplasmosis. In addition, *Pneumocystis jirovecii* has been included.

ASPERGILLOSIS

The pleural space occasionally becomes infected with *Aspergillus*, usually *Aspergillus fumigatus*.⁹⁸ Pleural aspergillosis

usually arises in one of two settings: in patients who were treated in the past with artificial pneumothorax therapy for TB and, less commonly, in patients following lobectomy or pneumonectomy, in which case a bronchopleural fistula is almost always present. Pleural aspergillosis has been described in a healthy individual.^{98a}

The diagnosis of pleural aspergillosis should be suspected in any patient with a history of artificial pneumothorax therapy for TB who has signs and symptoms of a chronic infection, such as weight loss, malaise, low-grade fever, and chronic cough. The chest radiograph reveals increasing degrees of pleural thickening and usually an air-fluid level in the pleural space, indicating the presence of a bronchopleural fistula.⁹⁸ In some patients, fungal balls may be evident in either the lungs or the pleural space. The diagnosis is confirmed by the demonstration of *Aspergillus* on fungal cultures of the pleural fluid. Patients with pleural aspergillosis almost always have positive precipitin blood test results for antibodies against *Aspergillus*.

The optimal treatment for pleural aspergillosis is likely to be a combination of surgical removal of the involved pleura and resection of the involved lobe or the entire ipsilateral lung and concomitant medical therapy, which may take the form of systemic therapy or topical antifungal treatment. Lung resection is usually necessary because the infection tends to invade and destroy the underlying lung. Surgery, if appropriate, should be performed as early as possible to avoid progressive destruction of the lung. Some patients with pleural aspergillosis are too debilitated to undergo a major surgical procedure. Such patients should undergo open drainage (Eloesser flap) with daily insertion of gauze impregnated with amphotericin B.⁹⁹

Systemic medical treatment is usually given both before and after surgery. A potential regimen is an initial 2- to 4-week period of therapy with amphotericin B, followed by longer-term administration of a more modern agent such as an azole. Treatment should continue for at least 6 months, although some patients may require much longer periods of treatment.¹⁰⁰ Topical pleural antifungal treatment may be used as an adjunct to systemic therapy.¹⁰¹

BLASTOMYCOSIS

Infection with *Blastomyces dermatitidis* produces a pleural effusion in about 10% of patients, and an additional 40% or more have pleural thickening.¹⁰² Patients with pleural blastomycosis have signs and symptoms similar to those of tuberculous pleuritis. The pleural fluid is usually an exudate with predominantly small lymphocytes, although polymorphonuclear leukocytes may predominate. Because pleural biopsy results may reveal noncaseating granulomas, one should consider the diagnosis of blastomycosis in patients with a clinical picture compatible with tuberculous pleuritis and granulomas on pleural biopsy. The diagnosis is established by demonstrating the organism in secretions, pleural fluid, or histologic sections. Patients with pleural blastomycosis should be treated with itraconazole or amphotericin B.

COCCIDIOIDOMYCOSIS

Two types of pleural disease are seen in association with coccidioidomycosis. The first is associated with a

primary benign infection and may or may not have concomitant parenchymal involvement. The second develops when a coccidioidal cavity ruptures to produce a hydropneumothorax.

Primary Coccidioidomycosis

The incidence of pleural effusion in hospitalized patients with primary coccidioidomycosis is about 15%.¹⁰³ Most patients are febrile and have pleuritic chest pain. The pleural effusion is almost always unilateral and can occupy more than 50% of the hemithorax.¹⁰³ There is a coexisting parenchymal opacity in about 50% of patients. The pleural fluid is an exudate containing predominantly small lymphocytes and frequently eosinophils.¹⁰³ At times the pleural fluid can be pus.¹⁰³ Pleural fluid cultures are positive for *Coccidioides immitis* in about 20%, with poor results also from polymerase chain reaction.¹⁰⁴ Cultures of pleural biopsy specimens, however, are almost always positive. Most patients with primary coccidioidomycosis and pleural effusion require no systemic therapy. The complement fixation titers are usually high in patients with coccidioidal pleural effusion, and a high titer alone should not be used as an indication for treatment. Only patients with prolonged or severe symptoms, evidence of dissemination, or those at a high risk for dissemination should be considered for first-line treatment with an azole.

Rupture of Coccidioidal Cavity

Hydropneumothoraces develop in 1% to 5% of patients with chronic cavitary coccidioidomycosis (see Fig. 37-6). The rupture of the cavity into the pleural space is usually heralded by the development of an acute illness with systemic signs of toxicity. These patients should undergo tube thoracostomy immediately to drain the air and fluid from the pleural space. Most patients require a thoracotomy with a partial or total lobectomy, and most require some degree of decortication.⁷⁷

CRYPTOCOCCOSIS

Pleural involvement with cryptococcosis appears to result from extension of a primary subpleural cryptococcal nodule into the pleural space. About 50% of patients with pleural cryptococcosis have disseminated disease, and most have an accompanying parenchymal abnormality. Most patients who have a cryptococcal pleural effusion are immunosuppressed, and many of the patients have *acquired immunodeficiency syndrome* (AIDS).¹⁰⁵ The pleural fluid is an exudate, usually with a predominance of small lymphocytes.

Not all patients with pleural cryptococcosis require treatment with systemic antifungal therapy.⁷⁷ Treatment should be initiated in patients with cryptococcal antigen in their blood or cerebrospinal fluid; in immunosuppressed patients, including those with AIDS; and in those with enlarging effusions, especially if pleural cell counts and LDH concentrations are increasing.⁷⁷

HISTOPLASMOSIS

Pleural effusion is rare with histoplasmosis. In one review of 259 patients with pulmonary histoplasmosis, only one had a pleural effusion.¹⁰⁶ Patients with pleural effusions

secondary to histoplasmosis usually have a subacute illness characterized by low-grade fever and pleuritic chest pain. The chest radiograph usually reveals an opacity or a subpleural nodule in addition to the pleural effusion.¹⁰⁷ The pleural fluid is usually a lymphocytic-predominant exudate, and the pleural biopsy may reveal noncaseating granulomas. No systemic treatment is usually necessary for a pleural effusion secondary to histoplasmosis because the effusion normally resolves spontaneously over several weeks. Systemic therapy should be administered if the effusion persists more than 3 to 4 weeks or if the patient is immunosuppressed.

PNEUMOCYSTIS JIROVECI

Pleural effusions are rare in patients with *P. jirovecii* pneumonia, but they have been reported. There is, however, no evidence to support the routine testing of pleural fluid for *P. jirovecii* except in the severely immunocompromised.¹⁰⁸ When there are pleural effusions, they appear to be an extension of the pulmonary process, and concurrent pneumothoraces are common (see eFig. 90-15). The pleural fluid is an exudate with a relatively low protein level but an LDH level above the upper normal limit for serum. At times, organisms can be visualized in the pleural fluid.

VIRAL INFECTIONS

Viral infections account for a sizable percentage of undiagnosed exudative pleural effusions. However, the diagnosis is rarely established because it usually depends on the isolation of the virus or the demonstration of a significant increase in antibody titers to the virus. These studies are not routinely obtained on patients with undiagnosed pleural effusions.

PRIMARY ATYPICAL PNEUMONIA

The incidence of pleural effusions with so-called primary atypical pneumonia (usually caused by *Mycoplasma* or viruses) is as high as 20%.¹⁰⁹ The effusions associated with atypical pneumonia are usually small, are exudative, and contain predominantly neutrophils. If there is sufficient fluid, as described earlier, thoracentesis should be performed to exclude a complicated parapneumonic effusion.

OTHER VIRUSES

Viral infection is probably responsible for a much higher percentage of pleural effusion without parenchymal opacities than is generally recognized. In one epidemic, 559 soldiers in Turkey had an acute febrile illness characterized by pleuritic chest pain and a mononuclear cell–predominant pleural effusion without parenchymal opacities. No pathogens were demonstrated, and it was assumed that this self-limited disease was due to a virus, although serologic studies were not performed.¹¹⁰

Almost all patients with the hantavirus pulmonary syndrome have a pleural effusion. Initially the fluid is a transudate, probably resulting from cardiac dysfunction, but subsequently the fluid becomes exudative.¹¹¹ Almost all

patients with severe cases of dengue hemorrhagic fever also have pleural effusions. Pleural effusions have also been reported to result from infection with hepatitis, infectious mononucleosis, respiratory syncytial virus, influenza viruses, measles after the administration of inactivated virus vaccine, cytomegalovirus, herpes simplex virus, and Lassa fever virus. Pleural effusions have not been a major feature of infection with Ebola virus.^{111a}

ACQUIRED IMMUNODEFICIENCY SYNDROME

Pleural effusions are seen in patients with AIDS but are less common than are parenchymal opacities. In one series of 1225 consecutive hospital admissions of patients with AIDS in Jacksonville, Florida, the incidence of pleural effusion was 15%.¹¹² The distribution of the diseases responsible for pleural effusions in patients with AIDS varies widely. In series from industrialized countries that included predominantly intravenous drug users, the most common cause is parapneumonic effusions; in series with predominantly homosexuals, the most common cause is Kaposi sarcoma; in series from Africa, the most common cause is TB. Other causes of pleural effusions in patients with AIDS include primary effusion lymphoma (see eFig. 90-37), *P. jirovecii*, opportunistic infections, renal failure, and congestive heart failure.

A patient with AIDS and parapneumonic effusions should be managed as any patient with a parapneumonic effusion would be managed, recognizing that the incidence of complicated parapneumonic effusion is higher in patients with AIDS.¹¹³ The incidence of pleural effusion with pulmonary Kaposi sarcoma is approximately 50% (eFig. 80-8). Most patients with a pleural effusion due to Kaposi sarcoma have bilateral parenchymal opacities (see eFig. 80-8B). The diagnosis of pleural involvement is difficult and often depends on the demonstration of pulmonary Kaposi sarcoma, either by bronchoscopic examination, high-resolution CT, or thoracoscopy. The pleural fluid is an exudate that is usually serosanguineous or hemorrhagic. Pleural fluid cytologic examinations are invariably negative with pleural Kaposi sarcoma; pleural biopsy results are also usually negative because the parietal pleura is not involved.

Patients with AIDS with an exudative pleural effusion should have a diagnostic thoracentesis that includes bacterial, mycobacterial, and fungal cultures and measurement of the pleural fluid ADA level. If this does not establish a diagnosis, consideration should be given to performing thoracoscopy, at which time a pleurodesis may be considered in symptomatic patients.

PARASITIC DISEASES

Parasitic infections of the lungs are discussed in Chapter 39. Those that may also involve the pleura—amebiasis, echinococcosis, and paragonimiasis—are also considered in this section.

AMEBIASIS

About 20% of patients with amebic liver abscess will develop pleuropulmonary complications.¹¹⁴ Pleural effusions arise

by two different mechanisms. First, an amebic liver abscess may irritate the diaphragm and produce a sympathetic pleural effusion in a manner analogous to that caused by a pyogenic liver abscess. Second, a pleural effusion develops when an amebic liver abscess ruptures into the pleural space through the diaphragm (see eFig. 33-29).¹¹⁵

The sympathetic effusion in amebic liver abscess is more common than rupture of an abscess through the diaphragm.¹¹⁵ The pleural fluid has not been well characterized. The diagnosis can be established by positive gel diffusion, indirect hemagglutination, or enzyme-linked immunosorbent assay tests, the results of which are positive in more than 98% of patients with extraintestinal invasive amebiasis.¹¹⁵ Patients with amebic abscess and a sympathetic pleural effusion should be treated with antiamebic drugs.

The transdiaphragmatic rupture of an amebic liver abscess is usually heralded by an abrupt exacerbation of pain in the right upper quadrant and may be accompanied by a tearing sensation.¹¹⁴ Shortly thereafter, progressive respiratory distress, sepsis, and occasionally shock develop. The pleural effusion is frequently massive, with opacification of the entire hemithorax and shift of the mediastinum to the contralateral side.¹¹⁴ The diagnosis of amebic abscess with transdiaphragmatic rupture is suggested by the discovery of “anchovy paste”-or “chocolate sauce”-like pleural fluid on diagnostic thoracentesis. Patients with transdiaphragmatic rupture should undergo urgent tube thoracostomy. The patients should also be treated with the same antiamebic drugs recommended for patients with amebic sympathetic effusions, such as metronidazole. Although the pus in amebic empyema is sterile,¹¹⁶ because bacterial infection of the pleural space complicates the process in about one third of patients, bacterial cultures of the pleural fluid should be obtained routinely. If bacterial infection is present, appropriate antibiotic therapy should be initiated.

ECHINOCOCCOSIS

Pleural involvement with hydatid disease can develop in one of three situations: (1) a pulmonary hydatid cyst may rupture into the pleural space, (2) a hepatic hydatid cyst or rarely a splenic cyst may rupture through the diaphragm into the pleural space, or (3) a hydatid cyst may slowly enlarge into the pleural space.¹¹⁷ When a cyst ruptures into the pleural space, either an empyema or a pneumothorax can result.¹¹⁷ In a series of 474 patients with pulmonary hydatid disease, 6% had pleural thickening or effusion.¹¹⁸

When a hydatid cyst ruptures into the pleural space, the patient develops acute symptoms, with sudden tearing chest pain, dyspnea, and shock from the antigenic challenge to the body. The cyst frequently also ruptures into the tracheobronchial tree, producing a bronchopleural fistula with a hydropneumothorax that may become secondarily infected.¹¹⁷

The diagnosis of pleural echinococcosis is established either by the demonstration of echinococcal scolices with hooklets in the pleural fluid or in the pleural biopsy specimen, or by a combination of serologic testing and radiology.

Lobulated cystic lesions in the pleural space may be seen on CT or magnetic resonance imaging.¹¹⁶ Eosinophils are frequently present in the pleural fluid unless it is secondarily infected. Patients with pleural echinococcosis should be immediately subjected to thoracotomy to remove the parasite, to excise the original cyst, and to close the bronchopleural fistula.¹¹⁷ Patients with hydatid cysts should be treated with antiprotozoal therapy if all the cysts cannot be removed, or if a cyst has ruptured. An alternative nonsurgical approach is PAIR therapy (puncture, aspiration, injection, and reaspiration), although this can cause allergic reactions.¹¹⁶

PARAGONIMIASIS

Pleural disease is common with paragonimiasis. In one series of 71 patients, 43 (61%) had pleural disease, including 20 with unilateral pleural effusions, 6 with bilateral pleural effusions, 6 each with unilateral and bilateral hydropneumothorax, and 5 with pleural thickening.¹¹⁹ Paragonimiasis can be found in natives of the United States who have never left the country.

Patients with pleural paragonimiasis present with a chronic illness. There is a concomitant parenchymal opacity in about 50% of patients. The pleural fluid in patients with pleural paragonimiasis is characteristic. It is an exudate with a glucose level of less than 10 mg/dL (0.56 mmol/L), an LDH level of more than three times the upper limit of normal for serum, a pH below 7.10, and a differential revealing a high percentage of eosinophils.¹²⁰ In addition, cholesterol crystals¹²⁰ or chyle¹²¹ may be present. Pleural paragonimiasis is one of only two conditions in which the pleural fluid is characterized by a low pH, a low glucose level, and many eosinophils; the other is eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome). Usually there are no ova in the pleural fluid.

The diagnosis of pleural paragonimiasis is strongly suggested by the unique pleural fluid findings, although in some cases lung biopsy may become necessary. The diagnosis is established definitively by demonstrating the typical operculated eggs in sputum, stool, or pleural fluid. A complement fixation titer above 1 : 8 for *Paragonimus westermani* is strongly suggestive of the diagnosis.¹²⁰ The treatment for paragonimiasis is discussed in Chapter 37.

Key Points

- The incidence of pleural infection is increasing globally in both adults and children for unclear reasons.
- Standard bacterial cultures are positive only in approximately 60% of pleural infection cases. Blood culture bottles can be combined with standard cultures to increase the yield.
- Community-acquired pleural infection is caused by a different range of organisms than hospital-acquired pleural infection and should be treated with different empirical antibiotics at presentation.
- The cornerstones of pleural infection management remain intravenous antibiotics, adequate drainage of the pleural collection, and adequate nutrition.

- A parapneumonic effusion with a pH of less than 7.20, a glucose level below 40 mg/dL, or significantly loculated pleural collection generally requires chest tube drainage to resolve the pleural sepsis.
- Surgical techniques such as video-assisted thoracic surgery have become widely available and can be offered to most patients if less invasive approaches are unsuccessful.
- Intrapleural tissue plasminogen activator plus DNase has been shown to improve the chest radiographic evidence of empyema and to decrease hospital length of stay. Its role needs to be evaluated further before its routine use can be recommended.

eFIGURE IMAGE GALLERY

Figure 80-1 Empyema: chest radiographic, ultrasonographic, and chest CT appearance. **A**, Frontal chest radiograph shows a large, homogeneous opacity, without air bronchograms, occupying the right thorax. **B–G**, Axial ultrasonographic images show a heterogeneous but predominantly hypoechoic collection (*single arrowheads*) in the right pleural space. The right diaphragm (*double arrowheads*) is visible; the complex fluid collection resides cranial to the diaphragm. The liver (L) is seen caudal to the complex fluid collection and diaphragm. Ultrasonographically guided thoracentesis yielded 250 mL yellow, cloudy fluid. The minimal amount of fluid that could be withdrawn was due to the presence of multiple loculations. **H–K**, Axial unenhanced chest CT shows multiloculated right pleural fluid associated with areas of smooth pleural thickening (*arrowheads*). Pleural fluid culture subsequently grew *Streptococcus intermedius*. (Courtesy Michael Gotway, MD.)

eFigure 80-2 Empyema: enhanced chest CT appearance. A–D, Contrast-enhanced chest CT in four different patients with empyema shows loculated pleural fluid collections with foci of smooth pleural thickening (*arrowheads*). Two of the cases (**A** and **C**) show gas-fluid levels (*arrows*), both before intervention, suggesting bronchopleural fistula. (Courtesy Michael Gotway, MD.)

eFigure 80-3 Eloesser flap: chest CT appearance. A–C, Axial enhanced (A and B) and unenhanced (C) chest CT images in three separate patients who underwent the Eloesser flap procedure, one for chronic empyema (A), one for treatment of bronchopleural fistula (B), and the other as part of surgery for mesothelioma (C). All three images show a clear connection between the thorax and exterior (arrow). The patient with mesothelioma (C) shows concentric pleural thickening. (Courtesy Michael Gotway, MD.)

eFigure 80-4 Tuberculous pneumonia and effusion presenting similarly to bacterial pneumonia and parapneumonic effusion. A, Frontal chest radiograph shows nonspecific left perihilar opacity and a hazy right base with increased attenuation. Left lower lobe consolidation obscuring the diaphragm is also present. The imaging findings are very nonspecific. B, Enhanced chest CT shows lingular (arrow) and left lower lobe consolidation with small, symmetric, nonspecific pleural effusions (arrowheads). Although the chest CT findings were ultimately shown to be due to *Mycobacterium tuberculosis*, the imaging findings are not specific for that diagnosis. (Courtesy Michael Gotway, MD.)

Figure 80-5 Tuberculous empyema: chest CT findings. A–C, Axial enhanced chest CT shows a large right pleural effusion with loculation (*arrowhead*), and smooth pleural thickening (*arrows*). The nondependent morphologic features and lenticular shape (seen in **A**), loculation (*arrowhead*), and smooth pleural thickening, representing the “split-pleura” sign, are all suggestive of empyema but are not specific for tuberculosis. (Courtesy Michael Gotway, MD.)

Figure 80-6 Tuberculous empyema: chest radiographic and chest CT findings. A, Frontal chest radiograph shows nonspecific medial right base consolidation. B–G, Enhanced chest CT displayed in soft tissue (B–E) and lung (F and G) windows shows a loculated, medial right thoracic pleural fluid collection (*arrow*) consistent with empyema. Necrotic and nodular medial right lower lobe lung parenchymal opacity (*arrowheads*) represents tuberculous infection. (Courtesy Michael Gotway, MD.)

eFigure 80-7 *Nocardia asteroides* pulmonary infection with pleural effusion. **A** and **B**, Axial enhanced chest CT displayed in lung windows shows bilateral lower lobe consolidation, cavitory on the right (*arrows*). Trace bilateral, nonspecific pleural effusions (*arrowheads*) are present. (Courtesy Michael Gotway, MD.)

eFigure 80-8 Pleural effusions in Kaposi sarcoma. **A** and **B**, Axial enhanced chest CT displayed in soft tissue (**A**) and lung (**B**) windows shows small, symmetric, bilateral pleural effusions (*arrowheads*). Enhancing right cardiophrenic angle lymphadenopathy (*arrow*) is present. The typical appearance of bilateral, patchy, poorly defined peribronchial nodular opacities is readily appreciated on the lung window images (**B**). (Courtesy Michael Gotway, MD.)

INTRODUCTION

A pneumothorax is present when there is air in the pleural space. Pneumothoraces are classified as *spontaneous pneumothoraces*, which develop without preceding trauma or other obvious cause, and *traumatic pneumothoraces*, which develop as a result of direct or indirect trauma to the chest, including diagnostic or therapeutic maneuvers (*iatrogenic pneumothoraces*). Spontaneous pneumothoraces are subclassified as *primary* or *secondary*. A *primary spontaneous pneumothorax* (PSP) presents in an otherwise healthy person without underlying lung disease. A *secondary spontaneous pneumothorax* (SSP) complicates an underlying lung disease, most commonly *chronic obstructive pulmonary disease* (COPD).

Most pleural effusions prove to be either an exudate or a transudate according to the criteria provided in Chapter 79. Occasionally the liquid contents turn out to be chyle, pseudo-chyle, or blood. This chapter describes the pathogenesis and clinical manifestations of chylothorax, pseudochylothorax, and hemothorax. Fibrothorax, the sequela of chronic organizing pleural disease of any origin, is also considered.

PATHOPHYSIOLOGY OF PNEUMOTHORAX

In normal subjects the pressure in the pleural space is negative with respect to the alveolar pressure during the entire respiratory cycle. The pressure gradient between the alveoli and the pleural space—the transpulmonary pressure—is the result of the inherent elastic recoil of the lung. During spontaneous breathing, the pleural pressure is also negative with respect to the atmospheric pressure. The functional residual capacity, or resting end-expiratory volume of the lung, is the volume at which the inherent outward pull of the chest wall is equal to, but opposite in direction to, the inward pull (recoil) of the lung.¹

When a communication develops between an alveolus or other intrapulmonary air space and the pleural space, air will flow from the alveolus into the pleural space until there is no longer a pressure difference or until the communication is sealed. Similarly, when a communication develops through the chest wall between the atmosphere and the pleural space, air will enter the pleural space until the pressure gradient is eliminated or the communication is closed. The influence of a pneumothorax on the volume of the

Figure 81-1 Influence of a pneumothorax on the volumes of the lung and hemithorax. In this illustration the pneumothorax has caused the intrapleural pressure to rise from -5 to -2.5 cm H_2O . The lung and thoracic cavity move on their respective pressure-volume curves to new volumes for the lung (A) and thoracic cavity (B). Note that the volume of the hemithorax becomes larger as the volume of the lung becomes smaller. The changes in volumes of the hemithorax and lung are unequal because of the differences in the slopes of two pressure-volume curves. VC, vital capacity. (Redrawn from Light RW: *Pleural diseases*, ed 4, Philadelphia, 2001, Lippincott Williams & Wilkins, p 286.)

hemithorax and the lung is illustrated in Figure 81-1. In this example, sufficient air has entered the pleural space to elevate the pleural pressure from -5 to -2.5 cm H_2O , so that the transpulmonary or recoil pressure has decreased from 5 to 2.5 cm H_2O . The amount of air necessary to effect this change in the pleural pressure can be seen to be equal to 33% of the patient's vital capacity: most of this pleural air (25% of the vital capacity) is accounted for by air displaced from the lung, and the rest is accounted for by the expansion of the thoracic cavity along its pressure-volume curve (by 8% of the vital capacity). The rise in the pleural pressure also causes a shift of the mediastinum to the contralateral side, an enlarged hemithorax, and a depressed hemidiaphragm. These findings are expected and do not necessarily indicate that a tension pneumothorax is present.¹

The main physiologic consequences of a pneumothorax are a decrease in the vital capacity (as illustrated in Fig. 81-1) and the arterial PO_2 . In patients with PSP, the decrease in the vital capacity is usually well tolerated. If the lung function of the patient is abnormal before the development of the pneumothorax, however, the decrease in vital capacity may lead to respiratory insufficiency with alveolar hypoventilation and respiratory acidosis.

Most patients with a pneumothorax have a reduced arterial PO_2 and an increase in the alveolar-arterial oxygen tension difference. In a series of 12 patients with spontaneous pneumothorax, the arterial PO_2 was below 80 mm Hg in 9 (75%) and was below 55 mm Hg in 2 patients, both of whom had SSP.²

The reduction in arterial PO_2 appears to be due to the creation of regions of the lung both with low ventilation-perfusion ratios and with absent ventilation (shunt), and occasionally due to alveolar hypoventilation. Norris and coworkers² reported that the average right-to-left shunt in their 12 patients with spontaneous pneumothorax was more than 10%. Larger pneumothoraces were associated

with greater shunts. When the pneumothorax occupied less than 25% of the hemithorax, the shunt was not increased.²

After air is evacuated from the pleural space, the arterial PO_2 usually improves, but the improvement may take several hours. Norris and colleagues² evacuated the pleural air from three patients with an initial shunt above 20%; within 90 minutes, the shunt had decreased below 10%, but it nonetheless remained above 5% in all patients. The delay in improvement may be related to the duration of the pneumothorax and the time necessary to expand collapsed alveoli.

PRIMARY SPONTANEOUS PNEUMOTHORAX

INCIDENCE

A study from Britain reported an incidence of spontaneous pneumothorax as 24.0 and 9.8 per 100,000 per year for men and women, respectively,³ and about one half of the pneumothoraces were PSPs. This extrapolates to an annual incidence of 22,500 in the United States.

ETIOLOGIC FACTORS

PSP, which develops in an otherwise healthy person without known lung disease, is traditionally believed to result from rupture of a subpleural emphysematous bleb often located in the apex of the lung.⁴ Blebs can be found in more than 75% of patients undergoing thoracoscopy for treatment of PSP.⁴ The pathogenesis of these subpleural blebs and the trigger(s) of their rupture are unclear. Such blebs have been attributed to congenital abnormalities, inflammation of the bronchioles, and disturbances of the collateral ventilation.⁴ There is a strong association between smoking and the development of a PSP. When four separate series of patients with PSP are combined, 461 of 505 patients (91%) with PSP were smokers or ex-smokers.¹ The risk for a spontaneous pneumothorax is related to the level of cigarette smoking. In men the relative risk for a pneumothorax is 7 times higher in light smokers (1 to 12 cigarettes per day), 21 times higher in moderate smokers (13 to 22 cigarettes per day), and 102 times higher in heavy smokers (>22 cigarettes per day) than in nonsmokers.⁵ It is probable that smoking-induced disease of small airways contributes to the development of the subpleural blebs.

Patients with PSP tend to be taller and thinner than control persons. In one study, military recruits with a pneumothorax were on average 2 inches taller and 25 pounds lighter than the typical military recruit.¹ An increased length of the chest may contribute to the formation of the subpleural blebs. Because pleural pressure falls about 0.20 cm H_2O per centimeter of vertical height, pleural pressure will be more negative at the apex of the lung in taller persons; accordingly, the alveoli at their lung apex are subjected to a greater mean distending pressure. Over an extended period, this could lead to the formation of subpleural blebs in subjects genetically predisposed to bleb formation.

The risks for PSP can be inherited. The Birt-Hogg-Dubé syndrome is an autosomal dominant condition characterized by an increased incidence of spontaneous pneumothorax (see Fig. 69-10), benign skin tumors, and renal tumors.⁶ The genetic abnormality resides on chromosome 17p11.2 and involves mutations in the folliculin gene.⁶ Approximately 40% of patients with the mutation will have a pneumothorax.⁶ Pneumothorax is also more frequent in those with the Marfan syndrome and homocystinuria.

The traditional concept was that air leaked from one bleb supplied by a single airway. More recent data have challenged this concept; a study using inhaled fluorescein suggested that air may leak from more areas than just the blebs,⁷ raising the possibility of “pleural porosity,” in which the air leaks from multiple pores on the visceral pleura. Endobronchial one-way valve studies also found that occlusion of multiple segmental bronchi are necessary to stop air leaks.⁸ This suggests that air is leaking either via multiple sites, via collateral ventilation, or both.

CLINICAL MANIFESTATIONS

PSP most commonly happens to those in their early 20s, and rarely after age 40. PSP usually develops while the patient is at rest, and rarely during heavy exercise.¹

Chest pain and dyspnea are the main symptoms. The chest pain, often acute, is usually localized to the side of the pneumothorax. Rarely, Horner syndrome can develop, probably from traction on the sympathetic ganglion associated with the mediastinal shift.

Vital signs are usually normal, with the exception of a moderate tachycardia. A tension pneumothorax should be suspected if tachycardia (>140 beats/min), hypotension, cyanosis, or electromechanical dissociation is present. The side with pneumothorax may be larger than the contralateral side and move less during the respiratory cycle. Tactile fremitus is absent, the percussion note is hyperresonant, and the breath sounds are absent or reduced on the affected side. In those with a right-sided pneumothorax, the lower edge of the liver may be shifted inferiorly. With a large pneumothorax, the trachea may be shifted toward the contralateral side.

DIAGNOSIS

The diagnosis is usually suggested by the clinical history and physical examination and established by demonstrating a pleural line on the chest radiograph (Fig. 81-2). A visceral pleural line can be distinguished from other lines such as skinfolds by the following criteria. This line is defined by air density on both sides of the line, whereas a skinfold is really an edge without air density on either side. A pleural line should generally be sharp and well defined, whereas a skinfold is often poorly defined, at least on one side. A pleural line can be followed continuously, roughly paralleling the chest wall inner contour so that, in the upright patient, it caps the apex of the lung (assuming no adhesions) and often tapers toward the lung base; a skinfold usually is not continuous, often fades at both ends, and often does not follow an anatomically sensible configuration. Finally, a

Figure 81-2 Distinguishing a pneumothorax from a skinfold. **A**, Chest radiograph of a pneumothorax. The pleural line has lucency on either side, representing air in the pleural space on one side of the line and air in the lung on the other. The line is sharply demarcated and can be traced along its course (lower arrow). No blood vessels can be seen beyond the superior (upper arrow) and lateral (middle arrow) extent of the line. **B**, Chest radiograph of a skinfold (arrows) that could be mistaken for a pneumothorax. The border is more of an edge, with lucency on only one side. The edge is poorly defined and cannot be followed continuously (lower arrow). Blood vessels can be traced beyond the border of the fold (arrowhead).

pleural line should not be crossed by lung vessels, whereas a skinfold can show lung vessels beyond its edge (eFig. 81-1).

In doubtful cases, lateral decubitus films (with the affected side up, eFig. 81-2), ultrasonography, or *computed tomography* (CT) (see Fig. 76-7) may facilitate the diagnosis. Expiratory films (see Fig. 18-5) are only slightly more sensitive than inspiratory films in detecting pneumothoraces and are not routinely recommended.⁴ A small pleural effusion is associated with a PSP in approximately 15% of cases and is manifested radiographically as an air-fluid level (eFig. 81-3; see eFig. 81-2). The pleural fluid frequently contains a large percentage of eosinophils.⁹ On rare occasions, spontaneous pneumothorax is complicated by brisk pleural bleed, producing a hemopneumothorax.¹⁰ Emergency surgery is indicated if the patient is hemodynamically compromised.¹⁰

When one is managing a patient with a pneumothorax, the amount of lung collapse should be estimated. One can first measure the lung and hemithorax “diameter”: the distance from the lung root to the visceral pleural line (lung diameter) or to the chest wall (hemithorax diameter). Because the volumes of the lung and the hemithorax are roughly proportional to the cube of their diameters, one can estimate the degree of collapse (percent pneumothorax, or PTX%) by measuring average diameters of the lung and the hemithorax, cubing these diameters, and using the following equation, known as the Light index¹:

$$\text{PTX}\% = 100\% \times [1 - (\text{diameter of the lung} / \text{diameter of the hemithorax})^3]$$

There is an excellent correlation ($r = 0.84$) between the Light index and the amount of air that can be aspirated from a pneumothorax.¹¹

RECURRENCE RATES

Following a PSP, a patient is at risk for recurrence particularly in the months immediately after the first episode. One study¹² followed 153 PSP patients for a mean of 54 months and reported that 39% had a recurrent ipsilateral pneumothorax, most within the first year. Interestingly, 15% also developed a pneumothorax on the contralateral side.

There have been several attempts to predict who will develop recurrent pneumothorax. Patients who are tall, patients with a low body mass index, and those who continue to smoke are more likely to have a recurrence.¹³ Patients who have blebs or bullae or both on high-resolution CT scan are also more likely to have a recurrence.¹⁴ Once a patient has had one recurrence, the risk for another recurrence increases to more than 50% if no measure is taken to prevent the recurrence.¹

TREATMENT

There are two goals to managing a patient with a PSP: to rid the pleural space of air and to prevent recurrence. Treatment options include observation, supplemental oxygen, simple aspiration, simple tube thoracostomy, tube thoracostomy with instillation of a pleurodesing agent, thoracoscopy with oversewing of the blebs and pleurodesis, and open thoracotomy. When selecting treatment for any given patient, it should be remembered that PSP is mainly a

nuisance and rarely life-threatening. Published guidelines, such as from the American College of Chest Physicians¹⁵ and the British Thoracic Society,¹⁶ have emphasized the lack of controlled studies on the treatment of pneumothorax.¹⁵

Observation

Once the communication between the alveoli and the pleural space is eliminated, the residual air in the pleural space will be gradually reabsorbed, albeit slowly. Kircher and Swartzel¹⁷ estimated that 1.25% of the volume of the hemithorax is absorbed each 24 hours. For a patient with a 20% pneumothorax, it will take 16 days for pleural air to be absorbed spontaneously. Supplemental oxygen may increase the rate of pleural air absorption (see the next section).

Supplemental Oxygen

In pneumothorax, gases move in and out of the pleural space from the capillaries in the visceral and parietal pleura. The movement of each gas depends on the gradient between its partial pressure in the capillaries and in the pleural space, the blood flow per unit surface area available for gas exchange, and the solubility of each gas in the surrounding tissues. Normally the sum of all the partial pressures in the capillary blood with a patient breathing room air is about 706 mm Hg (PN₂, 573; PH₂O, 47; PCO₂, 46; and PO₂, 40 mm Hg). If it is assumed that the pleural pressure is approximately 0 when there is a pneumothorax, then the net gradient for gas absorption is only 54 mm Hg (760 – 706). If the patient is placed on 100% oxygen, however, the sum of all the partial pressures in the capillary blood will probably fall below 200 mm Hg (the PN₂ will approach 0, whereas the PO₂ will remain <100 mm Hg). The net gradient for gas absorption will exceed 550 mm Hg, or be 10 times greater than it was with the patient breathing room air.¹

Administration of humidified 100% oxygen to rabbits with experimentally induced pneumothoraces increased the rate of absorption by about sixfold.¹⁸ In subsequent studies in patients with a spontaneous pneumothorax, administration of high concentrations of supplemental oxygen increased the rate of absorption by fourfold.¹⁹ It is recommended that hospitalized patients with any type of pneumothorax who are not subjected to aspiration or tube thoracostomy be treated with high-flow supplemental oxygen.

Simple Aspiration

The initial treatment for most patients with PSP greater than 15% of the volume of the hemithorax should be simple aspiration.^{16,20} This procedure is successful in about 60% of patients with PSP. If successful, simple aspiration avoids hospitalization, and there is less pain from the smaller tube. The recurrence rates appear to be similar after simple aspiration and after tube thoracostomy.^{16,20}

With this procedure, a relatively small needle (≈16 gauge) with an internal polyethylene catheter is inserted into the second anterior intercostal space at the mid-clavicular line after local anesthesia. An alternative site is selected if the pneumothorax is loculated or if adhesions are present. After the needle is inserted, it is extracted, leaving the catheter tip in the pleural space. A three-way stopcock and a

60-mL syringe are attached to the catheter. Air is manually withdrawn until no more can be aspirated. The catheter is then occluded for several hours. If the chest radiograph confirms that there has been no recurrence, the catheter is removed and the patient is discharged. Alternatively, the patient can be observed overnight or can be discharged with a Heimlich one-way valve attached to the catheter.^{20a} If the total volume of air aspirated exceeds 4 L and no resistance has been felt, it is assumed that there has been no reexpansion, and alternative procedures are initiated.

Patients with their first PSP should be managed initially with simple aspiration on an outpatient basis. Consideration can be given to overnight observation in hospital for those who reside a long distance from the hospital. Patients should return in 24 to 72 hours for a follow-up chest radiograph. If aspiration is unsuccessful, then either thoracoscopy or tube thoracostomy should be undertaken.²¹ In one study the intrapleural administration of 300 mg of minocycline after a successful pneumothorax aspiration decreased the incidence of subsequent PSP recurrence from 49% to 29%.²² Simple aspiration is not recommended for patients with secondary spontaneous pneumothoraces or with recurrent PSPs.

Tube Thoracostomy

For the past several decades, most patients with PSP have been managed initially with tube thoracostomy. It is recommended if simple aspiration proves ineffective and thoracoscopy is not readily available. It rapidly results in the reexpansion of the underlying lung and does not require prolonged hospitalization. In one series of 81 patients treated with tube thoracostomy, the average duration of hospitalization was only 4 days (range, 3 to 6 days). Only 3 patients (4%) had persistent air leaks after several days of chest tube drainage.²³

Tube thoracostomy with relatively small tubes (8 to 16 French) or pigtail catheters (8 to 10 French) appear to be as effective as larger tubes.¹⁶ It is advisable to use a water-seal chamber and to avoid suction for the first 24 hours of tube thoracostomy to reduce the risks of reexpansion pulmonary edema.

After the lung has reexpanded and the air leak has ceased for 24 hours, the chest tube can be removed. Air leaks are present when there is bubbling through the water-seal chamber of the drainage system. If there is no bubbling on quiet respiration, the patient should be asked to cough. The absence of bubbling indicates there is no air leak. Whether clamping the tube to observe for the recurrence of pneumothorax before its removal is beneficial remains controversial.¹⁵ If there is a persistent air leak after 72 hours, consideration should be given to application of a blood patch (see later). If air leak persists over 72 hours after tube thoracostomy, thoracoscopy should be considered.

Tube Thoracostomy with Instillation of a Pleurodesing Agent

Efforts have been made to diminish the recurrence rates of PSP by injecting pleurodesing agents into the pleural space at the time of the initial episode. Thoracoscopy with stapling of blebs and pleural abrasion reduces the recurrence rate to less than 5%²⁴ and is the preferred option. Otherwise, pleurodesis with talc slurry or doxycycline can reduce the

Figure 81-3 Pneumothorax recurrence. The probability of recurrent pneumothorax after assignment to the tetracycline group was lower than in the control group in the Veterans Administration cooperative study on spontaneous pneumothorax. (Redrawn from Light RW, O'Hara VS, Moritz TE, et al: Intrapleural tetracycline for the prevention of recurrent spontaneous pneumothorax. *JAMA* 264:2224–2230, 1990.)

recurrence rates from approximately 40% to 25% (Fig. 81-3).²⁵ Large-particle-size talc should be used to minimize the risks for acute lung inflammation.²⁶ A tetracycline derivative (e.g., doxycycline or minocycline) is preferred by some (see Chapter 82). Bleomycin is not recommended because it does not produce a pleurodesis in animals with a normal pleura²⁷ and has not been studied with pneumothorax in humans.

Autologous Blood Patch for Persistent Air Leak

The presence of a persistent air leak leads to prolongation of the hospitalization of patients with spontaneous pneumothorax. One inexpensive, noninvasive treatment for prolonged air leaks is the application of an autologous blood patch.^{28,29} Venous blood (50 to 100 mL) is drawn and promptly instilled intrapleurally, without anticoagulation, through a chest tube.²⁸ The chest tube should not be clamped because, with an ongoing air leak, there would be risk for tension pneumothorax. Elevating the tube (about 60 cm) keeps the blood within the pleural cavity without clamping. According to a review of the literature, the blood patch technique stopped the air leaks in 91.7% of 107 patients.²⁸ Whether blood patches prevent recurrence is unknown, although, in a small study ($n = 32$), no recurrences was found after a follow-up period of 12 to 48 months.³⁰

Thoracoscopy

Video-assisted thoracic surgery (VATS) is the treatment of choice of PSP if aspiration fails or if pneumothorax recurs (see Chapter 24). In a meta-analysis of 27 studies, the recurrence rate was only 5.4%.³¹ During VATS, attempts are made to eliminate the blebs (e.g., by endo-stapling or suturing³²) and to create a pleurodesis. Pleurodesis is probably best induced by pleural abrasion,^{33,34} but some recommend apical pleurectomy.³⁵ Bleb stapling without pleurodesis has a higher recurrence rate than bleb stapling with pleurodesis and is not recommended.

The most common complication after VATS for the treatment of PSP is a persistent air leak, seen in less than 5% of cases. VATS offers shorter hospitalization stays

(median, 3 days) and less morbidity when compared with thoracotomy.³¹

Medical thoracoscopy with talc insufflations (without stapling of blebs and pleural abrasion) has been tried.³⁶ In one study of 59 patients, this approach had a recurrence rate of 5% during a follow-up period of 5 years.³⁷ Controlled studies are needed to determine whether thoracoscopy is as effective as VATS.

Open Thoracotomy

When VATS is not available, open thoracotomy with oversewing of the blebs and pleural abrasion is a reasonable alternative. A transaxillary mini-thoracotomy can minimize the trauma and the length of the scar.³⁷ In a meta-analysis the recurrence rate after open thoracotomy was only 1.1% and significantly better than that for VATS.²⁴ Various methods have been used for scarification of the pleural surfaces, ranging from visceral and parietal pleurectomy to pleural abrasion with dry sponges. Because all appear to be similarly effective, pleural abrasion with dry gauze is recommended because it is less traumatic than pleurectomy and does not appear to interfere with a subsequent thoracotomy.

Summary of Treatment

Most patients with their first PSP should be managed initially with simple aspiration. Patients who fail aspiration should be managed with tube thoracostomy. If the air leak persists, VATS should be performed promptly, with endostapling of blebs and pleural abrasion to create a pleurodesis. When thoracoscopy is unavailable, a blood patch or an attempt at pleurodesis with a tetracycline derivative or talc can be tried. Thoracotomy is effective but involves longer hospitalizations and more postoperative morbidity. Patients with recurrent PSP should undergo VATS or thoracotomy.

SECONDARY SPONTANEOUS PNEUMOTHORAX

SSP, which develops in a patient with an underlying lung disease, is thus more serious than a primary pneumothorax because it further decreases the pulmonary function of a patient whose reserve is already diminished. In addition, the presence of the underlying lung disease makes diagnosis and management of the pneumothorax more difficult.

INCIDENCE

The incidence of SSP is similar to that of PSP.³⁸ There are an estimated 15,000 new cases of SSP annually in the United States. Men older than age 75 have the highest per capita rate of pneumothorax, 60 per 100,000 per year.³

ETIOLOGIC FACTORS

COPD is the most common underlying disease in patients with SSP, although almost every lung disease has been associated with SSP. In one series of 505 patients with SSP, 348

Figure 81-4 Chest CT scan of a patient with lymphangioleiomyomatosis. Note the numerous thin-walled cysts, rounded and relatively uniform in shape, and a pneumothorax on the left. (Courtesy Dr. Lisete Teixeira, University of Sao Paulo, Brazil.)

patients had COPD, 93 had tumors, 26 had sarcoidosis, 9 had tuberculosis, 16 had other pulmonary infections, and 13 had miscellaneous diseases.³⁹ Among patients with COPD, the incidence of SSP increases with progressive severity of the COPD. In the Veterans Administration cooperative study²⁵ on pneumothorax, 27% of the 229 participants had an FEV₁/FVC ratio below 0.40. One of the more common causes of SSP is *Pneumocystis jirovecii* infection in patients with *acquired immunodeficiency syndrome* (AIDS) (see eFig. 90-15).⁴⁰ There is also a high incidence in cystic fibrosis. Of the more than 28,000 patients on the Cystic Fibrosis Foundation registry, the incidence of pneumothorax was 3.4%.⁴¹ Patients with lymphangioleiomyomatosis (Fig. 81-4; see Chapter 69 and eFig. 69-7) and Langerhans cell histiocytosis (formerly histiocytosis X⁴²) (see Chapters 54 and 63) also have a high incidence of spontaneous pneumothorax.

CLINICAL MANIFESTATIONS

In general, the clinical features (dyspnea, chest pain, cyanosis, and hypotension) associated with SSP are more severe than those associated with PSP. In the Veterans Administration cooperative study, the mortality rate from pneumothorax was 1%.²⁵

DIAGNOSIS

The possibility of a pneumothorax should be considered in every patient with COPD who has a sudden increase in breathlessness and/or chest pain. Physical examination is not always helpful because patients with underlying disease may already have hyperexpanded lungs, decreased tactile fremitus, a hyperresonant percussion note, and distant breath sounds over both lung fields.

The demonstration of a pleural line on the chest radiograph can be difficult in radiographs of COPD patients because of their emphysematous lungs. Pneumothorax is therefore easily overlooked, particularly when the radiograph is overexposed. In patients with lung disease, the

Figure 81-5 Bullae resembling pneumothorax. **A**, Frontal chest radiograph of a patient with cystic fibrosis and extensive bullous disease of the right apex that was initially mistaken for a pneumothorax. Note lucent area (arrows) within the right upper lung field. **B**, CT scan confirms the presence of bullae (*) and excludes pneumothorax.

radiographic appearance of the pneumothorax can be altered by the underlying abnormalities. Areas of normal lung collapse more evenly and completely than do diseased areas with large bullae or severe emphysema, which have decreased elastic recoil and may trap gas.

It is important to distinguish a SSP from a thin-walled bulla in patients with COPD. The apparent pleural line with a large bulla is usually concave toward the lateral chest wall because it represents the medial border of the bulla, whereas the pleural line with a pneumothorax is usually convex toward the lateral chest wall. CT scanning may be necessary to diagnose pneumothorax in a patient with COPD and to discriminate between pneumothorax and bullae (Fig. 81-5).

RECURRENCE RATES

The recurrence rates for SSPs are higher than those for PSPs whether or not measures are taken to prevent a recurrence. In observation studies over a 3- to 5-year period, the recurrence rates were shown to be higher in those with SSP ($\approx 45\%$) than in patients with PSP ($\approx 30\%$).^{12,25}

TREATMENT

Urgent evaluation is indicated for any patient suspected of having a SSP, because death has been reported before a chest tube can be inserted. Such deaths were reported in 3 of 57 patients (5%) with pneumothorax secondary to COPD⁴³ and in 3 of 15 patients (20%) with cystic fibrosis.⁴⁴ The high immediate mortality rate emphasizes the need for prevention of recurrences.

If one has time, the initial treatment for nearly every patient with a SSP should be tube thoracostomy. Simple aspiration is not recommended except in an emergency (see later) because it frequently is ineffective and cannot prevent recurrence. The evacuation of even a small pneumothorax can rapidly improve symptoms. In patients receiving mechanical ventilation, immediate chest tube drainage is needed because the pneumothorax is likely to enlarge.

In SSP the lung is more difficult to expand and air leaks persist longer when compared with PSP. In SSP caused by COPD, the median time for lung expansion is 5 days (versus

1 day for PSP),⁴³ and more patients require prolonged chest tube drainage. After 7 days of tube thoracostomy drainage, the lung remains unexpanded or the air leak persists in about 20% of patients with SSP.⁴³

Following thoracostomy, most patients with SSP should be considered for thoracoscopy. Thoracoscopy should certainly be performed in patients with a persistent air leak or an unexpanded lung after 72 hours of tube thoracostomy. If the lung expands and the air leak ceases within the first 72 hours, an attempt should be made to prevent a recurrence. For preventing recurrences, thoracoscopy is superior to chemical pleurodesis (recurrence rates of about 5% versus 20%, respectively).^{12,25} If thoracoscopy is unavailable/inappropriate, chemical pleurodesis should be performed (as discussed earlier) to prevent a recurrent pneumothorax. A blood patch can be considered if thoracoscopy is unavailable and the patient has a persistent air leak.⁴⁵ Thoracotomy is another alternative.

One consideration for patients with SSP is the effect that a pleurodesing agent might have on future lung transplantation. In 1998, however, a consensus conference statement on lung transplantation in cystic fibrosis stated that pleurodesis is not a contraindication to lung transplantation.⁴⁶ However, pleurodesis is likely to make future lung transplantation more difficult, and consultation with a transplant surgeon is advisable.

PNEUMOTHORAX SECONDARY TO PNEUMOCYSTIS IN PATIENTS WITH AIDS

Patients with AIDS and *P. jirovecii* infection have a relatively high incidence of spontaneous pneumothorax. Approximately 5% of patients with AIDS who receive prophylactic pentamidine will have a spontaneous pneumothorax. Most patients with AIDS who have a spontaneous pneumothorax have a history of *P. jirovecii* infection, many are taking prophylactic pentamidine, and most have a recurrence of *P. jirovecii* infection.^{1,40} The presence of multiple subpleural lung cysts or cavities, often associated with subpleural necrosis, may explain the high incidence of spontaneous pneumothorax¹ (see eFig. 90-15). After having one pneumothorax, the patient is likely to experience a contralateral pneumothorax. It should be noted that iatrogenic

pneumothoraces, particularly those related to mechanical ventilation or pulmonary procedures, are also common in patients with AIDS.^{1,40}

Perhaps due to the necrotic lung surrounding the ruptured cavity, the spontaneous pneumothorax associated with AIDS and *P. jirovecii* infection is notoriously difficult to treat. In one report of 20 patients, the median duration of tube thoracostomy was 20 days; 11 patients underwent pleurodesis, whereas 5 patients had thoracotomy.⁴⁷

Patients with AIDS and a spontaneous pneumothorax should be treated with tube thoracostomy. If the air leak persists for more than a few days, there are two options: a Heimlich valve or VATS. There is no literature on use of the blood patch technique in managing these patients. In general, the Heimlich valve is preferred because the patient can be managed as an outpatient.

If the air flow is too high for the Heimlich valve to maintain lung inflation, VATS can be performed. Wait⁴⁸ reported that 30 of 32 patients with AIDS and spontaneous pneumothorax were managed successfully with talc insufflation without endo-stapling. If operative intervention is planned, it should be carried out early to avoid prolonged hospitalization and morbidity.

PNEUMOTHORAX SECONDARY TO TUBERCULOSIS

Between 1% and 3% of patients hospitalized for pulmonary tuberculosis will have a pneumothorax⁴⁹ (eFig. 81-4). All such patients should be treated initially with tube thoracostomy. In one series of 28 patients, 7 of the 11 patients treated by observation or repeated pleural aspiration died,⁴⁹ compared with 1 of the 17 patients treated with tube thoracostomy (64% versus 6%, respectively). Antituberculous chemotherapy should be given concomitantly with the tube thoracostomy. Thoracoscopy or thoracotomy should be considered if the lung remains unexpanded or if there is an air leak after 7 days.⁵⁰

IATROGENIC PNEUMOTHORAX

Iatrogenic pneumothoraces are probably more common than PSPs and SSPs combined. Currently, the leading cause of iatrogenic pneumothorax is transthoracic needle aspiration (see Fig. 19-10). The incidence of iatrogenic pneumothorax with this procedure is about 25%, and about 10% of the patients with pneumothorax receive tube thoracostomy.¹ This procedure is more likely to result in a pneumothorax if the patient has COPD, if the lesion is deep within the lung, or if the angle of the needle route is wide (which may correlate with an increased number of passes).^{51,52} Various maneuvers such as positioning the patient with the biopsied side down or using the blood patch technique have not consistently proved useful in diminishing the incidence of pneumothorax. One paper did demonstrate a significant reduction in pneumothoraces if the puncture access was sealed by instillation of NaCl 0.9% solution during extraction of the guide needle.⁵³

Mechanical ventilation is another risk factor. In one early series of 553 patients undergoing mechanical ventilation, 4% developed a pneumothorax.⁵⁴ The frequency of the

pneumothorax was increased if the patient had aspiration pneumonia (37%), was treated with positive end-expiratory pressure (15%), had intubation of the right main-stem bronchus (13%), or had COPD (8%).⁵⁴ In another study, the incidence of pneumothorax in 725 patients with acute respiratory distress syndrome was 6.9%.⁵⁵ In patients with acute respiratory distress syndrome, the incidence of barotrauma is higher if the ventilator plateau pressure exceeds 35 cm H₂O or if the lung compliance is below 30 mL/cm H₂O. In patients with asthma, barotrauma rates were high and mortality was similarly high; now both have been reduced by low-pressure permissive hypercapnic ventilatory strategies.

Other common causes of iatrogenic pneumothorax (with approximate incidences) are thoracentesis (2.5%), pleural biopsy (8%), and transbronchial lung biopsy (6%) (eFig. 81-5). Iatrogenic pneumothorax also frequently complicates *cardiopulmonary resuscitation* (CPR). Other procedures associated with the development of an iatrogenic pneumothorax include subclavian (eFig. 81-6) or internal jugular vein catheterization, tracheostomy, intercostal nerve block, mediastinoscopy, liver biopsy, and the insertion of small nasogastric tubes.¹ Radiofrequency ablation is increasingly used to treat lung tumors and carries a high incidence of pneumothorax (≈30%).^{56,57} In a series of 137 procedures, 27 resulted in symptomatic pneumothoraces requiring chest tube drainage.⁵⁸ In another series, the risk for pneumothorax was associated with the number of tumors ablated, electrode positions, and the electrode trajectory through aerated lung.⁵⁷

DIAGNOSIS

Iatrogenic pneumothorax should be suspected in any patient treated by mechanical ventilation whose clinical condition suddenly deteriorates. A sensitive indicator of the development of a pneumothorax in such patients is increased peak and plateau pressures if the patient is on a volume-cycled ventilator or a decreased tidal volume if the patient is on a pressure-cycled ventilator.

The diagnosis should also be suspected in any patient who becomes more dyspneic after an intervention procedure that has been associated with development of a pneumothorax. Importantly symptoms from the pneumothorax may not be evident for 24 hours or longer after the procedure.⁵⁹ The diagnosis needs confirmation by ultrasound or radiographic imaging. In patients with extensive pulmonary opacities, there may be little evidence of lung collapse, but the air in the pleural space may instead be indicated by the “deep sulcus” sign (Fig. 81-6).

TREATMENT

The treatment of iatrogenic pneumothorax differs from that of spontaneous pneumothorax in that preventing recurrence is not an issue. If the patient has minimal/no symptoms and the pneumothorax is small (e.g., <15% of the volume of the hemithorax), the patient can be observed. The administration of supplemental oxygen increases resolution rate (see earlier section). Otherwise, the procedure of choice is simple aspiration with a plastic catheter,⁶⁰ as described for PSP. If simple aspiration fails,

Figure 81-6 Appearance of pneumothorax in a supine patient. Detailed views of the right costophrenic angle from successive supine chest radiographs taken before (A) and after (B) the development of a pneumothorax. Both illustrations show diffuse infiltration in the right lower lung field. Note change in costophrenic angles (arrows) caused by air in the pleural space between the diaphragm and chest wall: the “deep sulcus” sign. Air in the anterior pleural space can also be recognized by an air-tissue interface (arrowheads).

tube thoracostomy should be performed. Small-bore chest tubes with Heimlich valves are quite effective in this situation.⁶¹

The management of patients with an iatrogenic pneumothorax secondary to positive-pressure mechanical ventilation should include urgent tube thoracostomy because tension pneumothorax can easily develop when the positive pressure forces air into the pleural space under high pressure until it exceeds atmospheric pressure. If the patient continues to receive mechanical ventilation, the chest tube should be left in place for at least 48 hours after the air leak stops. At times, a bronchopleural fistula is so large that a high percentage of the total inspired volume exits through the chest tube. The air exiting through the chest tube still provides effective ventilation, however, because it contains levels of carbon dioxide similar to those of exhaled gas.⁶² Two studies in adults^{63,64} have demonstrated that high-frequency ventilation does not consistently improve gas exchange or decrease air leak through the fistula.

TRAUMATIC (NONIATROGENIC) PNEUMOTHORAX

The incidence of pneumothorax after blunt trauma depends on the severity of the trauma. The incidence of pneumothorax exceeds 35% in some series.⁶⁵

MECHANISM

A traumatic pneumothorax can result from either penetrating or nonpenetrating chest trauma (see Figs. 76-4, 76-7, 76-8, and 76-10 and eFigs. 76-10 and 84-2). With penetrating chest trauma, the wound allows air to enter the

pleural space via the chest wall or via the visceral pleura from the tracheobronchial tree. With nonpenetrating trauma, a pneumothorax may develop if the visceral pleura is lacerated secondary to a rib fracture or dislocation. In the majority of patients with pneumothorax secondary to nonpenetrating trauma, however, there are no associated rib fractures. It is thought that the sudden chest compression abruptly increases the alveolar pressure, which may cause alveolar rupture. Air then enters the interstitial space and dissects toward either the visceral pleura or the mediastinum. A pneumothorax develops when either the visceral or the mediastinal pleura ruptures.

DIAGNOSIS AND TREATMENT

The diagnosis of pneumothorax is made by ultrasonography, chest radiography, or CT. A pneumothorax detectable on CT, but not on the chest radiograph, is called an *occult* pneumothorax¹ and accounts for about 40% of traumatic pneumothoraces⁶⁶ (see Fig. 76-7). In recent years, ultrasonography (see Chapter 20) performed by emergency department physicians or surgeons has been used increasingly to determine whether a pneumothorax is present.⁶⁶ Ultrasonography is more sensitive than supine chest radiographs in identifying pneumothoraces,^{66,67} but there are also false positives, particularly in patients with underlying lung diseases, especially COPD.⁶⁸

Most traumatic pneumothoraces should be treated initially with tube thoracostomy. If the patient has an occult pneumothorax or if the distance between the lung and chest wall does not exceed 1.5 cm, however, tube thoracostomy is probably not indicated unless the patient is receiving mechanical ventilation.⁶⁹ In one series, 333 patients with pneumothoraces less than 1.5 cm were initially managed without chest tubes, and only 33 (10%)

subsequently required tube thoracostomy.⁶⁹ When traumatic pneumothoraces are treated with tube thoracostomy, the lung usually expands and the air leak ceases within 24 hours.⁶⁹ If the leak persists for more than a few days, consideration should be given to performing thoracoscopy to identify and repair the site of the air leak.⁷⁰

Immediate thoracotomy is indicated for traumatic pneumothorax in two uncommon scenarios. The first is fracture of the trachea or a major bronchus (see eFig. 76-10 and 84-2), which usually presents together with an anterior/lateral fracture of one or more of the first three ribs and is associated with at least some hemoptysis.⁷¹ Fiberoptic bronchoscopy to search for a bronchial tear⁷¹ followed by its surgical repair usually restores full function of the distal lung.⁷¹

The second diagnosis to consider is traumatic rupture of the esophagus, which is almost always accompanied by a hydropneumothorax (see Fig. 84-7). A reliable screening test for esophageal rupture is measurement of the pleural fluid amylase concentration.⁷² If this level is elevated, contrast radiographic studies of the esophagus should be performed. It is important to establish the diagnosis of esophageal rupture expeditiously because the mortality approaches 100% if surgical treatment is not performed promptly.

AIR TRAVEL AND PNEUMOTHORAX

For patients who have suffered a pneumothorax, the Aerospace Medical Association suggests that flying be allowed 2 to 3 weeks after radiologic resolution of the pneumothorax.⁷³ One study of 12 patients with traumatic pneumothorax reported that the 10 patients who waited at least 14 days before travel were all asymptomatic in flight, whereas 1 of 2 patients who flew earlier than 14 days developed respiratory distress in flight with symptoms suggesting a recurrent pneumothorax.⁷⁴ However, a recent article suggested that patients who do not have a pneumothorax 48 hours after discharge can travel safely.^{74a}

NEONATAL PNEUMOTHORAX

A spontaneous pneumothorax is present shortly after birth in 1% to 2% of all infants, and the pneumothorax is symptomatic in approximately half of these.^{18,75} It is twice as common in male infants. Affected infants are usually full- or post-term and have a history of fetal distress requiring resuscitation or a difficult delivery with evidence of aspiration of meconium, blood, or mucus.¹⁸

There is a high incidence (19% in a series of 295 infants) of pneumothorax in infants with neonatal respiratory distress syndrome⁷⁶ (eFig. 81-7). Pneumothorax developed in 29% of those requiring intermittent positive-pressure ventilation with positive end-expiratory pressure, in 11% of those requiring continuous positive airway pressure, and in only 4% of those not requiring respiratory assistance.⁷⁶ In a series of more than 20,000 babies with birth weights between 401 and 1500 g (0.9 to 3.3 pounds) born in 1999, the incidence of pneumothorax was 6.3%, but, in those babies weighing less than 750 g (1.7 pounds), the incidence was 15%.⁷⁷

PATHOGENESIS

The development of a spontaneous neonatal pneumothorax is related to the mechanical problems of expanding the lung for the first time. During the first few breaths of life, the transpulmonary pressures average 40 cm H₂O, with occasional pressures as high as 100 cm H₂O.¹ At birth the alveoli usually open in rapid sequence, but, if bronchial obstruction is present from the aspiration of blood, meconium, or mucus, high transpulmonary pressures may lead to rupture of the lung. A transpulmonary pressure of 60 cm H₂O ruptures an adult lung,¹⁸ whereas a transpulmonary pressure of 45 cm H₂O ruptures a neonatal rabbit lung.¹

CLINICAL MANIFESTATIONS

With neonatal spontaneous pneumothorax, the signs vary from none to severe acute respiratory distress, depending on the size of the pneumothorax. With a small pneumothorax, there may be mild apneic spells with some irritability or restlessness. With a large pneumothorax, there may be severe respiratory distress with marked tachypnea, grunting, retractions, and cyanosis.¹⁸ In newborn babies the detection of pneumothorax by physical examination is often difficult because breath sounds are widely transmitted in the small neonatal thorax from the contralateral lung. The most reliable sign is a shift of the apical heart impulse away from the side of the pneumothorax.¹⁸ The diagnosis requires radiographic confirmation (see eFig. 81-7).

The development of a pneumothorax in a patient with neonatal respiratory distress syndrome is usually heralded by a change in the vital signs. In one series, cardiac arrest marked the development of the pneumothorax in 12 of the 49 patients; most of the other patients had a decrease in the blood pressure, pulse, or respiratory rate.⁷⁶ In another series, however, the earliest signs were an increase in the blood pressure, heart rate, or pulse pressure.⁷⁸ A pneumothorax in an infant with the neonatal respiratory distress syndrome is associated with mortalities exceeding 60% in some studies.

TREATMENT

An infant with a spontaneous pneumothorax who is asymptomatic or mildly symptomatic can be observed closely because the pneumothorax usually resolves within a few days. It is necessary to observe the patient closely in case the pneumothorax enlarges or a tension pneumothorax develops.¹⁸ Supplemental oxygen can hasten the resolution of the pneumothorax, but it should be administered with care because of the dangers of retrolental fibroplasia.¹⁸ Tube thoracostomy should be performed on any neonate who is more than mildly symptomatic. In one series of 76 infants with spontaneous pneumothorax, respiratory failure necessitated mechanical ventilation in 18, and pulmonary hypertension requiring either nitric oxide or extracorporeal membrane oxygenation developed in 7.⁷⁹ However, all the patients had complete resolution of their pulmonary compromise.⁷⁹ Tube thoracostomy should be performed in virtually all infants with the neonatal respiratory distress syndrome and pneumothorax, because the

Figure 81-7 Catamenial pneumothorax. Frontal chest radiograph from a 32-year-old woman showing a small right-sided pneumothorax (arrow). This was the fourth episode with onset during menses. (Courtesy Dr. Lewis S. Lehman, San Francisco.)

pneumothorax further compromises the ventilatory status and tends to increase in size.

CATAMENIAL PNEUMOTHORAX

A catamenial pneumothorax is a pneumothorax that develops in conjunction with menstruation (Fig. 81-7). Up until 2004, 229 cases had been reported,⁸⁰ but it is probably underdiagnosed and underreported. With catamenial pneumothorax, respiratory symptoms usually develop within 24 to 48 hours of the onset of the menstrual flow.⁸¹ Most pneumothoraces are right sided, but left-sided and bilateral pneumothoraces have been reported.⁸¹ Catamenial pneumothoraces tend to be recurrent. On average, patients have approximately five pneumothoraces before the diagnosis is recognized.

PATHOGENESIS

The pathogenesis of catamenial pneumothorax is unclear. When the syndrome was initially described,⁸² it was hypothesized that air gained access to the peritoneal cavity during menstruation and then entered the pleural cavity through a diaphragmatic defect. In a subsequent review of 28 patients who had undergone thoracoscopy, endometriosis, primarily diaphragmatic, was present in 18 and diaphragmatic perforations or nodules were present in 21.⁸³ It has been suggested that, with diaphragmatic endometriosis, the endometrial tissue undergoes cyclical necrosis leading to a diaphragmatic defect.⁸⁴ These authors concluded that diaphragmatic abnormalities play a fundamental role in the pathogenesis of catamenial pneumothorax.^{83,84} Alternatively, endometriosis of the visceral pleura could lead to alveolar pleural air leaks during menstruation.

DIAGNOSIS AND TREATMENT

Any woman who has a spontaneous pneumothorax within the first 48 hours of her menstrual period should be suspected of having a catamenial pneumothorax. The treatment of catamenial pneumothorax is aimed at treating endometriosis, known or suspected, by suppressing the ectopic endometrium. This can be attempted by suppression of ovulation with oral contraceptives or by suppression of gonadotropins with danazol or gonadotropin-releasing hormone to produce a medical oophorectomy.⁸⁰ Alternative treatments include thoracoscopy with stapling of blebs, closure of diaphragmatic defects and parietal abrasion or pleurectomy, or pleurodesis.⁸⁰ In one series, 28 patients were treated with removal of the diaphragmatic perforation and pleurodesis at thoracoscopy plus suppression of gonadotropins, and the recurrence rate was still 32%.⁸³

TENSION PNEUMOTHORAX

A tension pneumothorax is present when the intrapleural pressure exceeds the atmospheric pressure throughout expiration and often during inspiration as well.¹ Most patients who develop a tension pneumothorax are receiving positive pressure to their airways, either during mechanical ventilation or during resuscitation.¹ For a tension pneumothorax to develop in a spontaneously breathing person, some type of one-way valve mechanism must be present so more air enters the pleural space on inspiration than leaves the pleural space on expiration, and thus air accumulates in the pleural space under positive pressure.¹

PATHOPHYSIOLOGY

The development of a tension pneumothorax is usually heralded by a sudden deterioration in the cardiopulmonary status of the patient. This is probably related to the combination of a decreased cardiac output due to impaired venous return and profound hypoxia due to ventilation-perfusion mismatches. In mechanically ventilated sheep, an induced tension pneumothorax (mean pleural pressure of +25 cm H₂O) reduced the cardiac output from 3.5 to 1.1 L/min.⁸⁵ The arterial PO₂ also fell from a baseline value of 159 to 59 mm Hg. Comparable reductions in cardiac output and oxygen saturation were seen in pigs⁸⁶ and in dogs⁸⁷ following induction of tension pneumothoraces. Similarly, in patients on mechanical ventilation who develop tension pneumothorax, there is a large drop in the cardiac output.⁸⁸

CLINICAL MANIFESTATIONS

Tension pneumothorax most commonly develops in patients receiving positive-pressure mechanical ventilation or CPR.⁸⁹ Occasionally a tension pneumothorax will evolve during the course of a spontaneous pneumothorax or during hyperbaric oxygen therapy. Tension pneumothorax can develop from improper connection of one-way flutter valves with small-caliber chest tubes.⁹⁰

The clinical picture of a tension pneumothorax is often characterized by respiratory distress, cyanosis, marked

tachycardia, and profuse diaphoresis, marked hypoxemia and sometimes respiratory acidosis.

Tension pneumothorax should be suspected in patients receiving mechanical ventilation who suddenly deteriorate. In this situation the peak pressures on the ventilator usually increase markedly if the patient is on volume-type ventilation, whereas the tidal volumes decrease markedly if the patient is on pressure-support ventilation.¹ Tension pneumothorax should also be suspected in any patient undergoing CPR in whom ventilation becomes difficult. In one series of 3500 autopsies, an unsuspected tension pneumothorax was found in 12 cadavers; 10 had received mechanical ventilation, and 9 CPR.⁹¹ Tension pneumothorax should also be suspected in patients with a known pneumothorax who deteriorate suddenly or in patients who have undergone a procedure known to cause a pneumothorax.

DIAGNOSIS AND TREATMENT

A tension pneumothorax is a medical emergency. One should not waste time to establish the diagnosis radiologically because the clinical situation and the physical findings usually strongly suggest the diagnosis¹ (see Fig. 76-4 and eFig. 81-7). The patient should immediately be given high-flow supplemental oxygen. Once the abnormal hemithorax is identified, a small (14- to 16-gauge) catheter with needle should be immediately inserted into the pleural space through the second anterior intercostal space.¹ The catheter should be left in place and in communication with the atmosphere until air ceases to exit through the syringe. Additional air can be withdrawn from the pleural space with the syringe and the three-way stopcock. The patient should be prepared for immediate tube thoracostomy.

REEXPANSION PULMONARY EDEMA

Unilateral pulmonary edema (*reexpansion pulmonary edema* [RPE]) may develop in certain patients whose lung has been rapidly reinflated after a period of collapse secondary to a pneumothorax or a pleural effusion. Patients with RPE have various degrees of hypoxia and hypotension. On occasion the pulmonary edema becomes bilateral, and the patient requires intubation and mechanical ventilation. On rare occasions the syndrome has been fatal, including in otherwise healthy, young persons. The incidence of RPE is probably relatively low because there were no instances of RPE in the Veterans Administration cooperative study of more than 200 patients with spontaneous pneumothorax.²⁵ In a retrospective study of 320 episodes of pneumothorax, RPE developed in 3 patients (1.0%).⁹² A literature review in 1988 revealed 53 cases of RPE edema, which was fatal in 11 (21%) cases.⁹³ This is likely an overestimation, because nonfatal cases are less likely to be reported and many patients are asymptomatic.⁹⁴

PATHOPHYSIOLOGY

RPE appears to be due to increased permeability of the pulmonary vasculature. In both experimental animals and

humans, the edema fluid has a high protein content, suggesting that edema forms because of increased capillary leak rather than increased hydrostatic pressure. It has been hypothesized that the mechanical stresses applied to the lung during reexpansion damage the capillaries and lead to pulmonary edema. Reperfusion injury due to reactive oxygen species is another possibility. However, several animal studies⁹⁵⁻⁹⁸ demonstrated that the administration of reactive oxygen species-scavenging compounds such as dimethylthiourea, catalase, or superoxide dismutase all partially inhibit the neutrophilic infiltration associated with the development of RPE but do not impressively decrease the amount of edema in the experimental situation. Moreover, neutrophil depletion does not affect the amount of edema. For these reasons, mechanical stress on the lung is currently considered to be the most likely cause of RPE.

In humans, most cases of RPE develop when the pneumothorax or pleural effusion has been present for at least 3 days and when negative pressure has been applied to the pleural space. Similar findings have been confirmed in experimental animal studies.

CLINICAL MANIFESTATIONS

Patients with RPE typically have pernicious coughing or chest tightness during or immediately after tube thoracostomy or large-volume thoracentesis. The symptoms usually progress for 12 to 24 hours, and serial chest radiographs reveal progressive ipsilateral pulmonary edema (see Fig. 76-6), which may progress to involve the contralateral lung. Treatment is primarily supportive, with the administration of supplemental oxygen and diuretics, and intubation and mechanical ventilation when necessary. One report suggested that the syndrome could be aborted if the patient is treated with continuous positive airway pressure within the first hour of the development of the syndrome.⁹⁸ Chest tubes should be placed to underwater-seal drainage if the syndrome develops to avoid further aggravation with suction.

PREVENTION

Because RPE can be fatal, it is important to prevent it when possible. The possibility of its development should be considered in any patient with a large pneumothorax or pleural effusion subjected to tube thoracostomy or thoracentesis. When tube thoracostomy is performed for spontaneous pneumothorax, the tubes should initially be connected to an underwater-seal drainage apparatus rather than to negative pleural pressure. If underwater-seal drainage does not cause reexpansion of the underlying lung within 24 to 48 hours, then negative pressure can be applied to the pleural space.¹

When a thoracentesis is performed, the procedure should be terminated if the patient develops tightness of the chest or experiences coughing. In a series of 941 thoracenteses, including 119 that drained more than 1500 mL, opacities consistent with RPE were noted in only two patients (0.2%) from whom 1000 and 1200 mL of pleural fluid had been removed; neither was symptomatic or required treatment.⁹⁹ Thus, RPE is rare and rarely clinically significant.

Patients should be monitored during thoracentesis for symptoms, and, although pleural manometry has been recommended to follow pleural pressures, such approaches have not yet been shown to alter the incidence of this rare complication.

CHYLOTHORAX

Pleural fluid can be milky or turbid. When this cloudiness persists after centrifugation, it is almost always due to high lipid content in the pleural fluid. High levels of lipid can accumulate in pleural fluid through two separate mechanisms. In one, chyle enters the pleural space following disruption of the thoracic duct, producing a chylothorax (chylous pleural effusion). In the second, large amounts of cholesterol or lecithin-globulin complexes accumulate in a pleural effusion to produce a pseudochylothorax (chyliform or cholesterol pleural effusion).¹⁰⁰ It is important to recognize and differentiate these two conditions because their etiology and management are completely different.

PATHOPHYSIOLOGY

A chylothorax forms when the thoracic duct, which carries dietary fat in the form of chylomicrons, becomes disrupted. Chylomicrons are formed in the intestine, after which they enter the intestinal lacteal vessels and are then transported to the cisterna chyli. The thoracic duct, a 2- to 3-mm-wide thin-walled conduit, leaves the cisterna chyli and passes through the aortic hiatus of the diaphragm on the anterior surface of the vertebral body between the aorta and the azygos vein into the posterior mediastinum. The thoracic duct then ascends extrapleurally in the posterior mediastinum along the right side of the anterior surface of the vertebral column. Between the level of the fourth and sixth thoracic vertebrae, the duct crosses to the left side of the vertebral column and continues cranially to enter the superior mediastinum between the aortic arch and the subclavian artery and the left side of the esophagus. As a result, rupture of the thoracic duct in its caudal portion tends to produce right-sided chylothoraces, and rupture of the cranial portion of the duct tends to produce left-sided chylothoraces.¹⁰⁰ Once the thoracic duct passes the thoracic inlet, it arches above the clavicle and passes anterior to the left subclavian artery, vertebral artery, and thyrocervical trunk to terminate in the region of the left jugular and subclavian veins.

Although the route just described is the typical one, there are wide anatomic variations throughout the course of the duct. For example, duplication or even triplication of the thoracic duct is present in 40% of the population. Also, many collateral vessels and lymphaticovenous anastomoses are known to exist. Presumably these channels transport the chyle to the blood following therapeutic ligation of the thoracic duct. The wide range of anatomic variation and the multiple collateral channels render the thoracic duct at risk for injury, especially during thoracic surgery.¹⁰¹

Chyle, the liquid drained from the thoracic duct, is a milky, opalescent fluid that usually separates into three layers on standing: a creamy uppermost layer containing chylomicrons, a milky intermediate layer, and a dependent

layer containing cellular elements. Chyle is bacteriostatic,¹⁰⁰ not irritating, and not known to induce pleural thickening.

The thoracic duct normally conveys between 1500 and 2500 mL of chyle daily. Ingestion of fat can increase the flow of lymph in the thoracic duct by two to tenfold for several hours. Ingestion of liquid, but not protein or carbohydrate, also increases the flow, whereas starvation decreases chyle flow. The primary cellular component of chyle is the T lymphocyte. Prolonged loss of chyle can result in severe nutritional depletion, dehydration, electrolyte loss, and hypolipidemia, as well as depletion of T- and B-cell lymphocytes and immunodeficiency.¹⁰⁰

ETIOLOGY

Chylothorax can result from traumatic (including surgical) and nontraumatic causes: their relative frequencies vary among series. In a summary of five separate series totaling 143 patients, greater than 50% of chylothoraces were caused by tumors, especially lymphoma (Video 81-1), followed by trauma.¹ However, a single institute series of 203 patients revealed trauma/surgery as the most common (50%) cause compared to nontraumatic causes (44%).¹⁰²

The unpredictable anatomy of the thoracic duct and associated accessory lymphatics makes them vulnerable to injury during cardiovascular or thoracic surgical procedures, especially those involving the posterior mediastinum. Esophagectomy, for example, is complicated by chylothorax in 1% to 4% of cases.¹⁰³ Overall, the incidence of chylothorax after cardiothoracic operations is low (0.5% to 2.5%).^{104,105} Surgical procedures that involve mobilization of the left subclavian artery are particularly likely to be complicated by chylothorax. Transplantation of the lung and heart (or both) can sever the lymphatic drainage and result in chylothoraces.¹⁰⁶ Chylothorax has been reported to complicate a wide range of other operations, including esophagoscopy, stellate ganglion blockade, thoracic sympathectomy, high translumbar aortography, lung resections, thyroid surgery, spinal surgery,¹ and even gastric banding.¹⁰⁷ Bilateral chylothoraces can develop following bilateral neck dissection.¹⁰⁸ Chylothorax is common after surgical repair of congenital diaphragmatic hernia (incidence, 4.6% in a series of 1383 patients), especially if patch repair or extracorporeal membrane oxygenation is employed. Most (>80%) patients can be treated conservatively, and mortality is not increased.¹⁰⁹ To aid in the identification of the thoracic duct during surgery, ingestion of cream (to increase the flow and size of the thoracic duct) before high-risk operations (e.g., esophagectomy) has been advocated.¹¹⁰

Nonsurgical trauma can also lead to chylothorax. The thoracic duct may be disrupted with penetrating injuries involving the neck or thorax. Nonpenetrating trauma in which the spine is hyperextended or a vertebra is fractured can lead to chylothorax, particularly if the injury follows shortly after the ingestion of a fatty meal. Less impressive traumas such as weight lifting, straining, severe bouts of coughing or vomiting, childbirth, and vigorous stretching while yawning have been associated with chylothorax.¹⁰⁰ Chylothoraces secondary to closed trauma are usually on the right side, with the site of rupture in the region of the 9th or 10th thoracic vertebra.

Chylothoraces can also arise from transdiaphragmatic movement of chylous ascites.¹¹¹ Causes of chylous ascites include many of the causes of chylothorax. In addition, cirrhosis may be a cause of chyloascites and associated chylothorax. These chylothoraces are transudative, probably from dilution by low-protein cirrhotic ascitic fluid.

There are many other causes of chylothorax, but all together they account only for a small percentage of all chylothoraces. Lymphangioleiomyomatosis (see also Chapter 69) and other lymphatic abnormalities, such as pulmonary lymphangiectasis, yellow nail syndrome, lymph node enlargement, and lymphangitis of the thoracic duct can result in chylothorax, as can tuberous sclerosis, amyloidosis, mediastinal fibrosis, lupus, and Gorham syndrome. Elevated pressure of the venous system into which the thoracic duct drains (e.g., superior vena caval or subclavian vein thrombosis/obstruction) is another cause of chylothorax.¹⁰⁰ In postsurgical patients, those with central venous thrombosis were five times more likely to develop chylothorax.¹¹² Chylothorax accounts for about one fifth of pleural effusions in patients with superior vena cava syndrome.¹¹³

Chylothorax with no identifiable cause (5% to 10% of all cases) is labeled *idiopathic*. Lymphoma, however, must be excluded.

Fetal and Neonatal Chylothorax

Fetal chylothorax is an uncommon but important condition that requires monitoring and management to avoid serious complications, including spontaneous abortion or death after birth.¹¹⁴ Fetal chylothoraces are often termed *primary* fetal pleural effusions, because no obvious cause can be identified in most cases.¹¹⁴ Congenital lymphangiectasis is a rare condition that can produce fetal chylothorax.¹¹⁵ Cytogenetic analysis of the cells (mainly lymphocytes) may help detect underlying chromosomal abnormalities.

Chylothorax is the most common type of neonatal pleural effusion,¹¹⁴ with an incidence estimated at 1:15,000. Of note, the pleural fluid remains clear rather than milky until milk feeding begins.¹¹⁴ It may be a result of persistent fetal chylothorax¹¹⁴ but can also be due to developmental abnormalities of the thoracic duct or its rupture from trauma during delivery.¹¹⁶ Increased venous pressure, especially from congenital heart diseases or from thrombosis of central venous catheters, is another recognized mechanism of neonatal chylothorax.¹¹⁴ In many cases the chylothorax is idiopathic.

Mutations of several candidate genes have recently been linked with congenital chylothorax, including *integrin α_9* (*ITGA9*) and β_1 (*ITGB1*), vascular endothelial growth factor receptor 3 (*FLT4*, and *FOXC2*). The integrin $\alpha_9\beta_1$ is widely expressed in smooth muscles and is a receptor for extracellular matrix proteins and vascular cell adhesion molecule-1. Animal studies suggested that the α_9 subunit is required for the normal development of the lymphatic system, including the thoracic duct. Mice with homozygous null mutation of the α_9 subunit develop large bilateral congenital chylothoraces.¹¹⁷ An autosomal inheritance of a heterozygous missense mutation (c.1210G>A, p.G404S) of *ITGA9* has been found in four of five fetuses with chylothoraces who did not respond to prenatal pleurodesis but not in those who responded.¹¹⁸

The gene for vascular endothelial growth factor C was found to be important in tumor-related lymphangiogenesis and chyloascites formation in mice bearing ovarian carcinoma. Chy-3-mutant mice, which carry a chromosomal deletion that includes *Vegfc*, develop hypoplastic dermal lymphatic drainage and resultant chyloascites and lymphedema.¹¹⁹ Transgenic mice with mutations in the *Pi3kca* (*phosphoinositide 3-kinase*) gene also develop defective lymphatics and chyloascites.¹²⁰ *Rasa1* (also known as p120 RasGAP) is a Ras GTPase-activating protein that functions as a regulator of blood vessel growth in adult mice and humans. In mice, systemic loss of *Rasa1* resulted in early lethality caused by chylothorax with underlying extensive lymphatic vessel hyperplasia and leakage.¹²¹

CLINICAL MANIFESTATIONS

The symptoms, physical findings, and radiographic features of chylothorax are the same as those encountered in patients with comparably sized pleural effusions of any cause. Pleuritic chest pain and fever are rare because chyle is not proinflammatory. Chylopericardium or chyloascites can be present concurrently.

With nontraumatic chylothorax, insidious onset of dyspnea on exertion is common. With traumatic chylothorax, there is usually a latent period of 2 to 10 days between the trauma and the clinical presentation of the pleural effusion.¹²² During this latent period, chyle may accumulate in the posterior mediastinum to form a chyloma—visible radiologically as a posterior mediastinal mass¹—which eventually ruptures into the pleural cavity, giving rise to a chylothorax.

Neonatal chylothorax may present with respiratory distress in the first few days of life. Fifty percent of the infants have symptoms within the first 24 hours, whereas 75% have symptoms by the end of the first week. Most neonatal chylothoraces are either right sided or bilateral, but rarely left sided.¹¹⁶ There is a high frequency of neonatal chylothoraces in infants with hydramnios.¹¹⁶ Fetal chylothorax is often diagnosed only on ultrasonography.

The main threat to life with chylothorax is from external drainage leading to inanition. The daily loss of 1.5 to 2.5 L of fluid rich in protein, fats, electrolytes, and lymphocytes will rapidly render patients malnourished and immunocompromised.

DIAGNOSIS

The distinctive white, odorless, milky appearance should suggest the diagnosis, though chylothorax must be differentiated from empyema and pseudochylothorax (Fig. 81-8). In empyema, the milky appearance is caused by suspended leukocytes and debris, which will sediment upon centrifugation, leaving a clear supernatant. In both chylous and chyloform pleural effusions, the milky appearance is caused by high lipid levels, and the supernatant will remain cloudy after centrifugation. The lipids in chyloform effusion are cholesterol or lecithin-globulin complexes rather than chylomicrons (as in chylothoraces).¹²³ It should be emphasized that the pleural fluid with chylothorax can occasionally be bloody or even clear yellow. In one series only 44% of chylothoraces were milky.¹²⁴

Figure 81-8 Chylothorax pleural fluid before and after low-fat diet. **A**, Milky appearance of a chylothorax, with a triglyceride level of greater than 700 mg/dL and cholesterol less than 70 mg/dL. **B**, Clear appearance of pleural fluid obtained after a low-fat diet, along with a reduced triglyceride level in the fluid. (From Scholz GA, Sirbu H, Anders K, et al: Persisting right-sided chylothorax in a patient with chronic lymphocytic leukemia: a case report. *J Med Case Rep* 5:492, 2011.)

Pleural fluid and serum triglyceride and cholesterol levels should be measured. Pleural fluid from a chylothorax usually has a triglyceride level above 110 mg/dL (1.24 mmol/L), a ratio of the pleural fluid to serum triglyceride level of greater than 1.0, and a ratio of the pleural fluid to serum cholesterol level of less than 1.0.¹¹¹ However, fasting may significantly reduce the triglyceride level in the pleural fluid and produce false-negative results.¹²⁵ If doubt persists after the lipid measurements, one approach is to feed the patient a high-fat meal before sampling the pleural fluid. Alternatively, the demonstration of chylomicrons in lipoprotein analysis of the pleural fluid confirms the diagnosis of chylothorax.¹²⁶ The latter is particularly valuable if the triglyceride level is in the equivocal range (50 to 110 mg/dL). Rarely, a pleural fluid triglyceride level of less than 50 mg/dL has been found in chylothorax. It is important to differentiate chylous from chyloform pleural fluid (see later).

Typical chylous effusions are lymphocyte-rich effusions with exudative protein levels but low lactate dehydrogenase

Clipping or fibrin glue to the thoracic duct leak
Radiation therapy for mediastinal lymphoma

levels.¹²⁴ The electrolyte composition of chyle is similar to that of serum, and the protein content is usually around 3 g/dL. Transudative chylothorax is usually due to concurrent conditions (especially hepatic cirrhosis) known to produce transudates. An elevated lactate dehydrogenase level in chylothorax should raise concerns of concurrent conditions (e.g., infection).^{124,127} Magnetic resonance imaging can confirm the high fat signal, whereas chest CT may occasionally show low attenuation representing fat (eFig. 81-8 and Video 81-2) within the pleural effusion and support the diagnosis of chylothorax.

After establishing the diagnosis of a chylothorax, it is important to determine the cause. Because lymphoma is the most common (and treatable) cause of nontraumatic chylothorax, CT of the mediastinum and abdomen is mandatory to search for lymphadenopathy and is also useful in the diagnosis of lymphangioleiomyomatosis.

Bipedal lymphangiography or lymphoscintigraphy (e.g., with technetium-99m-labeled human serum albumin) is useful to help pinpoint the site of chyle leak along the thoracic duct.¹²⁸⁻¹³⁰ Direct lymph node puncture to inject dye is an alternative method favored by some.¹⁰¹ Lipiodol is an alternative dye that has some sclerosant effect and thus potential advantage in occluding the thoracic duct.¹⁰¹ Unenhanced magnetic resonance imaging¹³¹ or the combination of lymphoscintigraphy with three-dimensional magnetic resonance imaging can provide additional anatomic and functional details of the lymphatic channels.¹³² Pleural biopsy or thoracoscopy is not usually indicated in the workup of patients with a chylothorax because the pleura is generally not affected.

TREATMENT

General Approaches

Management strategies for chylothoraces should be directed toward (1) maintaining nutrition and reducing the flow of chyle, (2) relieving dyspnea by removing the chyle, and (3) closure of the defect (Table 81-1). No evidence-based guidelines exist for chylothorax management, which may in part depend on the clinical scenario (e.g., adult versus child,¹³³ traumatic versus nontraumatic) and the rate of chyle leak.

Maintaining Nutrition and Reducing the Flow of Chyle. The main dangers to the patient are malnutrition and immunodeficiency from removal of a large volume of chyle; hence it is important to initiate definitive treatment of the chylothorax promptly.

Regardless of the cause, closure of the thoracic duct leak may be facilitated by reducing the flow of chyle. This can be achieved by using parenteral hyperalimentation to provide nutrition. Alternatively, a low-fat diet with most fats in the form of medium-chain triglycerides can reduce chyle flow because the medium-chain triglycerides are absorbed directly into the blood¹⁰⁰ (see Fig. 81-8). Input from an experienced dietitian is recommended.

A range of compounds have been tested to hasten the closure of thoracic duct leak. Most studies have used octreotide (a somatostatin analogue) in postoperative pediatric patients in uncontrolled trials, but evidence on its use in adults and for nontraumatic chylothoraces is relatively scarce; large controlled studies are urgently needed. In a series of chylothoraces in 85 children, 85% responded to dietary manipulation. Somatostatin therapy was successful in half of the remaining 15% of cases, but no factors were identified to predict octreotide response.¹³⁴ The mechanism of its action is not clear but is believed to be related to a reduction of intestinal fat (especially triglyceride) absorption and increased fecal fat excretion.¹³⁵ Common side effects include flushing, nausea, and diarrhea. Other agents examined include etilefrine¹³⁶—a sympathomimetic drug that aimed to induce contraction of smooth muscles around the main thoracic duct—and factor XIII; the results of these agents need further verification.

Relieving Dyspnea by Removing Chyle. Thoracentesis or tube thoracostomy may be used initially, but every attempt should be made to minimize the duration of tube drainage to avoid malnutrition or immunosuppression.

Pleuroperitoneal shunts are advisable if the chylothorax fails to resolve quickly. This minimizes the risks for malnourishment or immunodeficiency because the lymph is not removed from the body. Some authors recommend pleuroperitoneal shunts as the first line of management as soon as the diagnosis is established. To date, most series on pleuroperitoneal shunts are based in pediatric populations. Pleuroperitoneal shunting is contraindicated if ascites is present and is less likely to be successful if the chylothoraces result from central venous thrombosis.¹³⁷ Redirection of the chyle back into the systemic circulation has been performed successfully via pleurovenous shunts.¹³⁸ Use of indwelling pleural catheters for ambulatory drainage of chylothoraces has been reported in several retrospective small series.¹³⁹

Closure of the Defect. With traumatic chylothorax, the defect in the thoracic duct frequently closes spontaneously. Conversely, nontraumatic chylothorax is more likely to require surgical intervention.¹⁴⁰ In one series ($n = 74$), chylothorax resolved with medical (nonsurgical) measures in 50% of traumatic but only 27% of nontraumatic cases. In addition, chylous effusion recurred more commonly in nontraumatic chylothorax (50% versus 13% in traumatic cases). Lymphatic imaging did not seem to materially influence management.¹⁴¹

If the pleuroperitoneal shunt is ineffective in draining the pleural space, or if the patient has a chest tube and the drainage of chyle continues unabated beyond 7 days, a more aggressive treatment plan is needed. In a series of 27 patients with chylothorax following lung resection, those with large-volume drainage (>500 mL per 24 hours) despite total parenteral nutrition were more likely to require reoperation.¹⁰⁵ In another series of patients with post-lung resection chylothorax, 13 of the 15 patients with lower initial drainage volume (mean, 300 mL/day) responded to conservative treatment, whereas only 6 of 11 patients with larger drainage volume responded.¹⁴²

Several options exist to control the chyle leak. Talc pleurodesis by slurry or poudrage has been successful in some reports.¹⁴³ Recently, lymphatic embolization and blockade¹⁰¹ has been shown in several series, with a complete or partial response rate of approximately 70%.¹⁴⁴⁻¹⁴⁶ The thoracic duct is punctured transabdominally via a peritoneal cannula under fluoroscopic guidance, and the duct is embolized with various devices (e.g., microcoils). In patients whose thoracic duct cannot be cannulated, disruption of the duct with needles may be sufficient to reduce or stop the chyle leak.¹⁴⁴ Retrograde embolization of the cisterna chyli has been attempted via a microcatheter passed through the thoracic duct for the treatment of chylous ascites.¹⁴⁷ Coils, gelatin sponge, and doxycycline have been used as embolization material.¹⁴⁷

Surgical repair of the thoracic duct defect should be considered if lymphatic embolization is unavailable or fails. Surgical ligation can often be achieved via VATS, but thoracotomy is sometimes required. Laparoscopic and laparotomy approaches have also been tried. The duct is ligated above and below the site of the leak or at the lowest point in the chest.¹⁴⁸ Various technical advances have been tried, including fibrin glue application around the leak,¹⁴⁹ use of robotic ligation,¹⁵⁰ and thermofusion of the thoracic duct using a computer-controlled diathermy system.¹⁵¹ Ligation of the thoracic duct by laparoscopy has also been attempted with success.¹⁵²

Ideally, the site of the leak should be identified preoperatively by lymphangiography or lymphoscintigraphy. The identification of the thoracic duct can also be facilitated with preoperative oral administration of cream.¹⁵³

If for technical reasons the thoracic duct cannot be successfully ligated during VATS, a pleurodesis (e.g., partial pleurectomy or talc insufflation) should be performed to obliterate the pleural space during the operation. Mediastinal radiation therapy was successful in a pilot study ($n = 7$) of post-thoracic surgery chylothorax.¹⁵⁴

Special Considerations

Nontraumatic Chylothorax. If the patient is known to have either lymphoma or metastatic carcinoma, the chylothorax can respond to mediastinal radiation. In one series, mediastinal radiation adequately controlled the chylothorax for the remainder of the patient's life in 68% of those with lymphoma and in 50% of those with metastatic carcinoma.¹⁵⁵ If radiation therapy fails, embolization, pleurodesis, or pleuroperitoneal shunting should be considered.¹⁵⁶

If the cause of a nontraumatic chylothorax is unknown, the initial management is similar to that for a patient with a traumatic chylothorax, as discussed previously. A

pleuroperitoneal shunt may be considered to allow time for a thorough evaluation. If chest CT and lymphangiography have normal findings, the chylothorax can be assumed to be due to minor trauma, and spontaneous closure can be expected within weeks.

Fetal and Congenital Chylothorax. Congenital chylothorax, diagnosed either in utero or after birth, can cause developmental abnormalities and at times be fatal.¹¹⁴ Congenital chylothorax was present in 3.2% of 598 patients with hydrops fetalis in one series, with a mortality of 5.9%.¹⁵⁷ If diagnosed in utero, maternal dietary restriction should be initiated.¹⁵⁸ Ultrasound-guided thoracentesis can be performed to evacuate the chylothorax,¹⁵⁹ because large effusions can cause pulmonary hypoplasia and respiratory distress at birth.¹¹⁴ If the chylothorax reaccumulates, pleuro-amniotic shunting should be considered.¹⁶⁰ In a small number of reported cases, ultrasound-guided intrapleural administration of OK-432¹⁶¹ or maternal blood¹⁶² has offered effective control of the chylothorax, presumably via creating a pleurodesis.

If the congenital chylothorax is diagnosed after birth, the baby should be treated conservatively with repeated thoracenteses to avoid respiratory compromise while nutrition is maintained by the parenteral route or with medium-chain triglycerides.¹⁶³ Feeding with centrifuged breast milk (which removes the fat content) was attempted in one small study.¹⁶⁴ Although the evidence supporting octreotide remains limited, it has a good safety profile and can be tried. If the chylothorax recurs after the third pleural aspiration, however, a pleuroperitoneal shunt should be placed. If the shunt is unsuccessful, thoracic duct ligation is recommended.¹¹⁴ In one study of congenital chylothoraces ($n = 10$), those with lower birth term and birth weight and whose drainage exceeded 50 mL/kg/day were more likely to fail to respond to conservative treatment and require surgery.¹⁶⁵

Pulmonary Lymphangioleiomyomatosis. Pulmonary lymphangioleiomyomatosis (LAM) is a rare condition, affecting mostly women of reproductive age, and is characterized by progressive dyspnea, recurrent pneumothoraces, and chylous effusions (see Chapter 69). The reported incidence of chylothorax in patients with LAM ranges from 10%¹⁶⁶ to 30%.¹⁶⁷ It can arise in both the sporadic and the tuberous sclerosis complex-associated types of LAM—the former is associated with a higher incidence of chylothorax.¹⁶⁶ Whereas the mean age of presentation of LAM is in the early 30s,¹⁶⁸ the mean age of presentation of chylothorax is in the early 40s.¹⁶⁶ The chylothorax is usually unilateral but can be bilateral¹⁶⁶ or associated with chyloascites. The chylothorax is thought to be the result of the combination of perilymphatic proliferation of smooth muscle leading to lymphatic obstruction and of infiltration of the lymph nodes in the mediastinum and retroperitoneal space by immature smooth muscle cells.¹⁶⁹ CT scan is usually diagnostic for LAM (see Fig. 8.1-4). Typical LAM cell clusters can also be found in the chylous pleural fluid.¹⁷⁰

The general principles for the management of a chylothorax secondary to LAM are similar to those for any non-traumatic chylothorax. The course of these chylothoraces is highly variable.¹⁶⁶ In some cases, simple thoracentesis for

symptomatic relief is adequate.¹⁶⁶ However, in two series combined, 12 of the 19 LAM patients with chylothoraces required either pleurodesis or thoracic duct ligation to control the reaccumulation of chyle.^{166,171} In one series, sirolimus successfully controlled the chylous effusions in 12 patients with improvement in lung function.¹⁷²

When considering use of pleurodesis, one should consider the potential impact on future lung transplantation, which is a treatment option for a proportion of patients with LAM (19% in one series¹⁷³). The morbidity and mortality of transplantation is already increased in these patients, especially from intraoperative bleeding¹⁷⁴ attributed to pleural adhesions from recurrent pneumothoraces, and pleurodesis may increase that risk. Although pleurodesis is not an absolute contraindication for future transplantation, a transplant surgeon should be consulted before subjecting LAM patients with a chylothorax to pleurodesis or surgical ligation of the thoracic duct.

PSEUDOCHYLOTHORAX (CHYLIFORM PLEURAL EFFUSIONS; CHOLESTEROL PLEURAL EFFUSIONS)

A pseudochylothorax (chyliform pleural effusion) may also produce milky turbid pleural fluid. The turbidity is related to high levels of cholesterol or lecithin-globulin complexes in the fluid. Pseudochylothoraces, with fewer than 200 reported cases in the literature,¹⁷⁵ are much less common than chylothoraces.

PATHOGENESIS

Although pseudochylothorax was first reported over a century ago, its precise pathogenesis remains unknown. Most patients with a pseudochylothorax have pleural surfaces that are markedly thickened and sometimes calcified, and the effusion is usually long-standing. It appears that, if an exudative effusion persists for a lengthy period—months to years—in a fibrotic area of grossly thickened pleura, it has a high tendency to become enriched with cholesterol.¹⁰⁰ However, increasing reports of pseudochylothoraces without chronic pleuritis or grossly thickened pleura challenge the traditional belief.¹⁷⁶

Most of the cholesterol in chyliform pleural effusions is associated with high-density lipoproteins, in contrast to the cholesterol in acute exudates, which is mostly bound to low-density lipoproteins.¹⁷⁷ It has been hypothesized that, during acute inflammation, there is increased filtration of cholesterol into the pleural fluid.¹⁷⁷ In addition, the cholesterol can originate from degeneration of erythrocytes and leukocytes that enter the pleural space as part of the underlying disease process.¹⁷⁸ The thickened pleura inhibits the exit of cholesterol out of the pleural space.¹⁷⁷ Serum cholesterol levels and systemic cholesterol metabolism appear to be normal in patients with pseudochylothorax.

Chyliform pleural effusions are most commonly seen after tuberculous pleurisy (54%), including those cases treated with artificial pneumothorax. Successful treatment

of an acute tuberculous pleurisy does not preclude the development of a pseudochylothorax.¹⁷⁵ Pseudochylothorax can develop in association with chronic rheumatoid pleurisy (9% of pseudochylothoraces) and rarely with paragonimiasis and trauma (including thoracic surgery).¹⁷⁹

CLINICAL MANIFESTATIONS

Pseudochylothorax commonly but not inevitably develops in patients with long-standing pleural effusions. The mean duration of the effusion is 5 years before it turns chyliform, but much shorter times of onset have been reported.^{176,180} Many patients with chyliform pleural effusions are asymptomatic or at least no more symptomatic than before they developed the pleural effusion. Symptoms, if present, are usually related to the underlying disease process or to the pulmonary restriction produced by the effusion and the thickened pleura. In some cases the effusion gradually enlarges with time, with resultant progressive dyspnea.¹⁰⁰

DIAGNOSIS

The pleural effusion is often chronic and associated with thickened or calcified pleura. The fluid is milky, and the differential diagnoses of chylothorax and empyema need exclusion (see earlier). Presence of cholesterol crystals in the fluid defines a pseudochylothorax. The cholesterol crystals give a distinct satin-like sheen to the pleural fluid and microscopically have a typical rhomboid appearance. Not all patients with chyliform pleural effusion have cholesterol crystals in their pleural fluid; however, most have an elevated pleural fluid cholesterol level (>250 mg/dL, or 6.45 mmol/L).¹ Pleural fluid triglyceride levels can be high in pseudochylothorax. CT chest scan can reveal a layering of fat in nondependent sites.¹⁸¹

TREATMENT

Tuberculosis should always be considered in patients with a pseudochylothorax, although tuberculous pseudochylothorax is usually culture negative.¹⁷⁵ We advise drainage only in symptomatic cases and treating with antituberculous chemotherapy only those patients with positive stain or culture for tuberculosis and those with enlarging effusions of suspected tuberculous origin (see Chapter 35).

When the patient's exercise capacity is limited by breathlessness, a therapeutic thoracentesis should be performed and may improve exercise tolerance.¹⁷⁸ Thoracentesis can be difficult because of the frequently thickened pleura and negative intrapleural pressure.¹⁰⁰ Limited evidence exists to support surgical decortication, which should be considered only if the patient is symptomatic and the underlying lung is believed to be functional.

HEMOTHORAX

Hemothorax is the presence of blood in the pleural space, specifically when the hematocrit of the pleural fluid is greater than or equal to 50% of that of the peripheral blood.¹ When bloody pleural fluid is obtained with a diagnostic thoracentesis, the hematocrit should always be

measured. Frequently, even though the pleural fluid appears to be pure blood, the hematocrit of the fluid is below 5%.¹

TRAUMATIC HEMOTHORAX

Blood may enter the pleural space from injury to the chest wall, diaphragm, lung, blood vessels, or mediastinum. On entering the pleural space, the blood coagulates rapidly, but, presumably as a result of the physical agitation produced by movement of the heart and lungs, the clot may be defibrinated, rendering it liquid and unable to clot again. Loculation may develop early in the course of hemothorax.

Diagnosis

The diagnosis of traumatic hemothorax should be suspected in any patient with penetrating or nonpenetrating trauma of the chest (Fig. 81-9; see eFig. 76-8). It should be emphasized that the hemothorax may not be apparent on the initial chest radiograph. In one series of 130 patients with hemothorax secondary to nonpenetrating trauma, the hemothorax was not appreciated on the initial chest radiograph in 24% of the patients.¹⁸² Although the hemothorax was missed in some of the patients because the initial radiograph was obtained with the patient supine, other patients had no evidence of a hemothorax on the erect radiograph.¹⁸²

The CT scan is more sensitive than the chest radiograph in detecting hemothoraces. In a study of 103 patients with blunt trauma,⁶⁵ chest CT detected a hemothorax in 21 patients (20%) in whom the routine chest radiograph showed no pleural fluid. When patients experience severe thoracic trauma, a CT scan of the chest is indicated for its ability to identify hemothorax, as well as pneumothoraces, lung contusion, and bone fractures.⁶⁵

Ultrasonography is now used in many emergency departments and was comparable to initial chest radiograph in detecting hemothoraces in one study ($n = 240$, specificity

Figure 81-9 Frontal chest radiograph from a patient who suffered multiple injuries in an automobile accident. The patient had a hemothorax. With the prompt institution of tube thoracostomy, the air and blood were evacuated from the pleural space and the chest radiograph was normal 1 week later.

Figure 81-10 Axial CT scan of a patient with a large left hemothorax. The hyperdense region (arrows) indicates a retracted thrombus. Occasionally, unclotted erythrocytes can settle to the dependent area, creating a “fluid-fluid level,” representing the so-called hematocrit sign (see eFig. 81-9B).

100% and sensitivity 96%).¹⁸³ On CT scans, hyperdensity, due to the high hemoglobin content of retracted clot or sedimented blood, may point toward a hematoma (Fig. 81-10).¹⁸⁴

Delayed hemothorax was reported in one third of 36 patients at 18 hours to 6 days following the initial blunt trauma, especially those with multiple or displaced rib fractures.¹⁸⁵ However, in another series of 100 patients with penetrating thoracic trauma, none developed a hemothorax after 3 hours.¹⁸⁶

A patient with a traumatic hemothorax should undergo immediate tube thoracostomy, which helps evacuate the blood from the pleural space, brings the two pleural surfaces into apposition (which some believe may retard bleeding), enables quantification of the blood loss, and may decrease the incidence of subsequent empyema. The blood drained from the pleural space may be autotransfused, although contents of a hemothorax have a lower concentration of hemoglobin and coagulation factors than fresh blood.¹⁸⁷

Wherever possible, chest tubes should be inserted under image guidance to avoid injuring the ipsilateral hemidiaphragm, which may be elevated because of other causes such as atelectasis or phrenic nerve paralysis. Large-bore chest tubes have traditionally been recommended to avoid clotting of the blood, although this has not been proven. Observational series have shown no significant differences in clinical outcomes in patients treated with drains of 28 to 32 French (compared with those treated with 36 to 40 French).¹⁸⁸ Chest tubes should be removed as soon as they stop draining or cease to function to reduce risks of pleural infection.

No precise threshold exists for the amount of pleural bleeding that should trigger surgical intervention; however, if the bleeding is greater than 200 mL/hr with no signs of slowing, surgery must be considered. VATS has largely replaced thoracostomy as the procedure of choice,¹⁸⁹ with thoracotomy reserved only for massive acute hemorrhages. No relationship between timing of VATS and success rate was identified in a study of 328 patients. Independent

predictors of the need for thoracostomy (and failure of VATS) included diaphragm injury, retained hemothorax greater than 900 mL, and not administering antibiotics for initial chest-tube placement.¹⁹⁰

In a series of patients with active hemothorax, those with drainage above 200 mL/hr were subjected to contrast-enhanced CT scan, which identified sites of bleeding intercostal arteries. Subsequent transcatheter arterial embolization successfully stopped the bleeding.¹⁹¹

Complications

The four main potential pleural complications of traumatic hemothorax are the retention of clotted blood in the pleural space, pleural infection, pleural effusion, and perhaps fibrothorax. In one retrospective series, 24 (1.4%) of 1728 chest trauma patients had a residual hemothorax.¹⁹² Most patients with small to moderate amounts of clotted blood remaining in their pleural space have no residual pleural abnormalities even if no intervention is undertaken.¹⁹³ If more than 30% of the hemithorax is occupied by clotted blood, the hemothorax should be evacuated. Decisions regarding thoracoscopic evacuation should not be made from the plain chest radiograph alone and require CT studies.¹⁹⁴ VATS is the mainstay of management, and conversion to thoracostomy is seldom required.¹⁸⁹ The clotted blood should be evacuated within 7 days because after this time it begins to become organized and is much more difficult to remove.¹⁸⁹ In a prospective, randomized trial, VATS was more effective than thoracostomy tube drainage for removing retained hemothoraces. In this study, both the length of hospital stay (7 vs. 3.6 days) and the duration of tube drainage (4.5 vs. 2.5 days) were shorter in the group receiving VATS.¹⁹⁵ In another series, thoracoscopic evacuation performed within 3 days of admission was associated with a lower operative difficulty score (and shorter operation time) and shorter inpatient stay, compared with patients operated at later time points.¹⁹²

Once the source of the bleeding is controlled, intrapleural administration of fibrinolytic agents (e.g., streptokinase or urokinase) may be safe in patients with hemothorax and retained clots, according to several descriptive studies.¹⁹⁶ However, there have been no comparative studies to confirm the efficacy of fibrinolysis versus conservative management or surgical evacuation.

Empyema develops in 1% to 4% of all patients with traumatic hemothoraces,^{193,197} especially for those admitted in shock or those who have gross pleural contamination, associated abdominal injuries, or prolonged pleural drainage.^{193,197} For those with posttraumatic retained hemothorax, the risk for empyema was as high as 26.8% in a multicenter prospective study ($n = 328$).¹⁹⁸ The presence of rib fractures, Injury Severity Score of 25 or higher, and the need for additional interventions to evacuate retained blood from the thorax were predictors of empyema. Prophylactic antibiotics (e.g., cefazolin 500 mg every 6 hours until tube removal) can decrease the incidence of pleural infection,¹⁹⁹ which should be treated similarly as postpneumonic pleural infection (see Chapter 80).

In more than 10% of patients with a traumatic hemothorax, a pleural effusion will develop after the chest tubes are removed.^{193,197} Most such pleural effusions resolve spontaneously, leaving no residual pleural abnormalities. It is

important to perform a diagnostic thoracentesis in such patients, however, to verify sterility.

It is thought that fibrothorax develops in less than 1% of patients with hemothorax. Fibrothorax appears to develop more frequently when a hemopneumothorax is present or when a hemothorax becomes infected. The definitive treatment for fibrothorax is decortication. Decortication for fibrothorax should be delayed for several months after the injury, however, to allow time for spontaneous resolution of the pleural thickening, which is often considerable.

IATROGENIC HEMOTHORAX

The most common cause of iatrogenic hemothorax is thoracic surgery,²⁰⁰ but perforation of a central vein or artery by a percutaneously inserted catheter²⁰¹ is also common. Iatrogenic hemothorax can also follow thoracentesis (eFig. 81-9), pleural biopsy, chest tube insertion, percutaneous lung aspiration or biopsy (see eFig. 19-1), transbronchial biopsy, endoscopic esophageal variceal therapy, or CPR. Patients with iatrogenic hemothoraces should be managed, as are patients with traumatic hemothoraces, with chest tubes and thoracoscopy or thoracotomy as needed.

NONTRAUMATIC HEMOTHORAX

Nontraumatic hemothoraces are distinctly uncommon. The most common cause is malignant pleural disease, and the second most common cause is a complication of anticoagulation therapy for pulmonary embolization.²⁰² The cause of the hemothorax in some patients remains unknown despite exploratory thoracotomy.

A spontaneous hemothorax may result from rupture of an abnormal intrathoracic blood vessel, such as subpleural arteriovenous malformations, aneurysm of the aorta or pulmonary artery, patent ductus arteriosus, or coarctation of the aorta. Other causes of a spontaneous hemothorax include a complication of bleeding disorders (such as hemophilia or thrombocytopenia), a complication of spontaneous pneumothoraces, bronchopulmonary sequestration, thoracic endometriosis, varicella pneumonia, or intrathoracic extramedullary hematopoiesis. Spontaneous hemothorax is a rare but potentially life-threatening complication of neurofibromatosis, either from aneurysmal changes in large arteries (e.g., aorta) or from dysplastic changes in small vessels.

Mediastinal tumors can also produce a spontaneous large hemothorax, which can be bilateral. Blood can also accumulate in the pleural space because of pathologic conditions of abdominal organs, such as rupture of a splenic artery aneurysm through the diaphragm, pancreatic pseudocysts, and rupture of hepatocellular carcinomas.

Hemothoraces can complicate anticoagulant therapy (warfarin²⁰³ or heparin—low molecular weight²⁰⁴ or unfractionated²⁰²) or intrapleural fibrinolytic therapy.²⁰³ The hemothorax usually becomes apparent 4 to 7 days after anticoagulation therapy is initiated, but it may happen much later. When the hemothorax develops, the coagulation study results may be within the acceptable therapeutic range.²⁰²

Chest tubes should be inserted into patients with spontaneous hemothorax to remove the blood from the pleural

space and to quantify the rate of bleeding. If brisk (>100 mL/hr) bleeding persists, emergency thoracotomy should be performed.

FIBROTHORAX

Pleural fibrosis usually follows intense inflammation of the pleura; however, the mechanisms following the inflammatory process leading up to fibrosis are unclear (Video 81-3). Profibrotic cytokines, especially *transforming growth factor-β* (TGF-β), probably play a significant role. In various animal models, TGF-β, administered directly or via vector transfection, induces pleural fibrosis, and anti-TGF-β antibodies can inhibit pleural adhesion formation in empyema.²⁰⁵

A fibrothorax most commonly develops as a complication of an empyema or a hemothorax, but can also complicate tuberculosis, collagen vascular diseases, uremia, paragonimiasis, drug reactions, and other pleural injuries. The pleura can also be involved in systemic fibrotic diseases such as nephrogenic systemic fibrosis and immunoglobulin G4-related sclerosing disease.²⁰⁶ Pleural fibrosis can be idiopathic, and isolated familial cases have been reported.²⁰⁷

Whereas tuberculous pleuritis is common, fibrothorax is a rare complication.²⁰⁸ In one study, restrictive functional sequelae were found in 10% of 81 patients with tuberculous pleuritis, but were mostly mild.²⁰⁹ Neither the early drainage of the pleural effusion²¹⁰ nor the use of systemic corticosteroids²¹¹ has significant impact on subsequent development of pleural thickening or restrictive lung function in patients with tuberculous pleuritis. Pleural fluid inflammatory markers are, at best, weak predictors of eventual pleural thickening.²⁰⁹

Asbestos exposure may also lead to a fibrothorax (also called diffuse pleural thickening), which is usually bilateral.²¹² In these cases, extensive fibrosis of the visceral pleura develops, together with areas of adhesion with the parietal surfaces, thus obliterating the pleural space.²¹² Diffuse pleural thickening is known to follow benign asbestos pleural effusions, and it has been suggested that this is a necessary precursor of fibrothorax.²¹³ In one series of 44 patients with diffuse pleural thickening, half had a history of benign asbestos effusion; conversely, 54% of those who had a benign asbestos effusion had residual pleural thickening.²¹³ Diffuse pleural thickening is usually,²¹² but not inevitably, associated with heavy asbestos exposure (see eFig. 73-14), and its incidence increases with increasing time since first exposure.²¹³ The pleural fibrosis is often progressive, resulting in restrictive lung defects, especially if the costophrenic angle is obliterated.²¹⁴

Pleural fibrosis (with or without concurrent pulmonary fibrosis) can also develop with the use of ergot alkaloids (e.g., bromocriptine, pergolide, and methysergide).^{203,215} It has been suggested that subjects with asbestos exposure may be more susceptible to bromocriptine-induced pleural fibrosis.²¹⁶ Onset of dyspnea from ergot-induced pleural fibrosis is usually insidious and in the majority of cases presents at least 6 months after starting the medication.²⁰³ The pleural thickening is usually bilateral but can be unilateral and may be associated with pleuritic pain. Constitutional symptoms and elevated serologic inflammatory markers have also been reported.²¹⁵ In the case of

bromocriptine, the fibrothorax will stop progressing on cessation of the drug use, and may regress,²⁰³ though complete resolution is rare. Corticosteroids are often administered, but their effectiveness has never been established.²⁰³ Pleural fibrosis is often bilateral (if due to systemic causes) and may be associated with concurrent peritoneal fibrosis.²¹⁷

Idiopathic pleuroparenchymal fibroelastosis is a group of disorders recently reported.²¹⁸⁻²²¹ It is characterized by progressive fibrotic thickening of the pleura and subpleural parenchyma, often in the upper lobes, and not associated with any known causes of fibrothorax. Dyspnea, cough, and recurrent infections are common.²¹⁸

Carbon nanotubes, which have many features similar to asbestos fibers, have caused alarm recently by being shown to stimulate significant pleural and subpleural/lung fibrosis in animal studies.²²² These nanotubes have high tensile strength and high length-width ratio and, upon inhalation, can migrate from distal alveoli to the pleural cavity.^{223,224} The long-term safety of carbon nanotubes, especially in humans, is under intensive research.

Although pleural fibrosis is usually an undesirable event, it is commonly used therapeutically (pleurodesis) to control pleural effusions and pneumothoraces. Pleurodesis is the iatrogenic induction of pleural fibrosis, leading to symphysis of the visceral and parietal pleurae to obliterate the pleural space to prevent fluid or air reaccumulation.²²⁵ Interestingly, pleurodesis has no major impact on pulmonary function, even after decades. A retrospective review of young patients treated 22 to 35 years ago for spontaneous pneumothoraces showed that those who received talc pleurodesis ($n = 80$) had a higher incidence of pleural thickening on radiographs, but minimal restrictive changes in their lung function when compared with those treated by simple drainage ($n = 34$).²²⁶ Several small human and animal studies also revealed no significant impairment in

lung volumes and gas exchange at rest or during exercise following pleurodesis.²²⁵ Such observations imply that, for a fibrothorax to be clinically significant, it must involve either very extensive pleural fibrosis (in excess of therapeutic pleurodesis) or concomitant parenchymal fibrosis.

DIAGNOSIS

In one large population screening study of over 70,000 subjects, pleural thickening was reported in 3.6% of radiologic examinations.²²⁷ The diagnosis of fibrothorax can typically be made from the radiographic findings plus a history of a predisposing cause (e.g., an old injury or infection) (eFigs. 81-10 to 81-12). Radiologically, a peel of uniform thickness surrounds the lung. Calcification, which is frequently seen on the inner aspect of the peel (Fig. 81-11; see eFig. 81-12), can provide an indicator by which the thickness of the peel may be accurately measured. Apparent pleural thickening can be seen, especially in obese subjects (body mass index > 30), presumably the result of extrapleural fat deposition.²²⁸ A CT scan can easily discriminate between fat and thickening.

A CT scoring system that quantifies the thickness of the pleura and the fractional circumference of the hemithorax involved (as well as other pleural changes, such as rounded atelectasis and pleural plaques) has been shown to correlate with impairment in pulmonary function measures (especially total lung capacity and diffusing capacity).²²⁹

Routine pulmonary function testing usually reveals mild to severe restrictive ventilatory dysfunction.²¹³ In the case of asbestos-induced diffuse pleural thickening, the restriction arises from inflammatory involvement of the costal surfaces of the diaphragm and lower costal pleura, thus producing a pleurodesis that limits the movement of both the diaphragm and rib cage during inspiration.²³⁰ The

Figure 81-11 Fibrothorax. Detailed views from frontal (A) and oblique (B) chest radiographs of a 62-year-old man showing a localized fibrothorax with calcified plaque on the right. The patient had a right-sided empyema 32 years before. (From Hinshaw HC, Murray JF: *Diseases of the chest*, Philadelphia, 1980, WB Saunders, p 912.)

Figure 81-12 Diffuse pleural thickening. Chest radiograph of a man with a strong history of asbestos exposure, progressive dyspnea, and a restrictive picture on pulmonary function testing. The radiograph showed bilateral diffuse pleural thickening (between arrows), blunting of the costophrenic angles, and calcified diaphragmatic plaque on the right (arrowheads).

reduction in rib cage expansion is the main cause of restriction, because the diaphragm can still contribute by flattening of its dome on inspiration.²³⁰ In one study, 95% of patients with asbestos-induced diffuse pleural thickening complained of exertional dyspnea.²³¹ Objective reduction of exercise work capacity had also been shown.²³²

Pulmonary function may be severely compromised in patients with an extensive fibrothorax (Fig. 81-12). With marked pleural thickening, the hemithorax becomes contracted, the intercostal spaces narrow, and the mediastinum may be displaced ipsilaterally. In severe, especially bilateral cases of fibrothorax, hypercapnic respiratory failure may develop and may necessitate noninvasive ventilation.²³³

TREATMENT

It should be emphasized that patients with a recent hemothorax, empyema, or tuberculous pleuritis frequently show marked spontaneous improvement in their symptoms and the degree of pleural thickening in the 3 to 6 months after the acute episode.²³⁴ Patients with a fibrothorax should avoid drugs that can induce pleural fibrosis.

Decortication—surgical removal of the fibrous peel from the pleural surface—has been attempted to treat fibrothorax. However, the degree of improvement after decortication varies, with many series showing disappointing results.^{235,236} Success in part depends on the condition of the underlying lung. If the underlying lung is normal, the vital capacity may improve after decortication, but, if there is extensive parenchymal disease, the vital capacity may even decrease. The duration of the fibrothorax does not predict outcome. Surgical morbidity and mortality are not insignificant.²³⁷ Therefore decortication should be considered only in patients with significant pleural fibrosis (with

relatively preserved underlying lung parenchyma) whose quality of life is limited by exertional dyspnea. The results of decortication in patients with bilateral fibrothoraces secondary to asbestos exposure have been disappointing, probably a result of concomitant pulmonary fibrosis.²³⁸

Key Points

- Simple aspiration is the recommended first step of air evacuation in most cases of primary spontaneous pneumothorax.
- Secondary spontaneous pneumothorax is potentially life-threatening, and prevention of recurrence should be considered even at the first episode of pneumothorax.
- Chylothorax is characterized by milky fluid and the presence of chylomicrons. Early intervention to control the chylothorax is advocated because prolonged drainage of chylous effusion can lead to malnutrition.
- Pseudochylothorax is characterized by cholesterol crystals and should be differentiated from chylothorax because the etiology and management are different.
- A traumatic hemothorax should be drained and, if the bleeding rate is greater than 200 mL/hr, intervention targeting the underlying bleeding site by surgical or interventional radiologic means should be considered. Traumatic hemothorax can be complicated by retention of clotted blood in the pleural space, pleural infection, pleural effusion, and perhaps fibrothorax.
- Pleural thickening may improve spontaneously during the 3 to 6 months after acute hemothorax, empyema, or tuberculous pleuritis. Decortication should be considered only if the pleural thickening has been present for several months and if the patient has significant exertional dyspnea.

SOLITARY FIBROUS TUMOR OF THE PLEURA**PRIMARY EFFUSION LYMPHOMA****PYOTHORAX-ASSOCIATED LYMPHOMA****INTRODUCTION**

Tumors of the pleural space can be primary or secondary. The secondary tumors from metastatic spread of malignancy are the most common and are discussed first. Pleural metastatic disease is estimated to affect 200,000 persons per year in the United States and represents the second most common cause of exudative pleural effusion (after infection).¹ Unfortunately, because it represents metastatic spread, the treatment goal is that of palliation, not cure. Survival is poor, with a median of 4 months.² The primary tumors of the pleural space are less common. The most common primary tumor, malignant mesothelioma, affects approximately 15,000 persons per year worldwide and 3000 per year in the United States, and its incidence is growing.¹ Interestingly, despite its grim reputation, mesothelioma offers better survival than does metastatic pleural disease, with a median survival of 12 months.³ Although curative treatments are not yet available, progress is being made. Other rare but interesting tumors such as solitary fibrous tumor of the pleura, primary effusion lymphoma, and pyothorax-associated lymphoma are discussed.

METASTATIC PLEURAL DISEASE**TYPES OF TUMOR**

Certain tumors appear to have a predilection for metastasis to the pleura, particularly lung cancer, breast cancer, and lymphomas, and less commonly gastrointestinal and genitourinary malignancies (Table 82-1). In approximately half the cases of metastatic pleural disease, the patient will have an associated pleural effusion, most often exudative.⁴ However, in up to 10% of the malignant pleural effusions, the tumor of origin is never identified.⁵

The pattern of metastatic spread can provide some clues to the identity of the primary tumor. Whereas malignant mesotheliomas generally originate on the parietal pleura and then spread to the visceral pleura, metastases due to bronchogenic carcinoma or other cancers usually are first found on the visceral pleura and then spread to the parietal

pleura; they are rarely found exclusively on the parietal pleura.^{4,6} In addition, in most cases of bronchogenic carcinoma, the side of a malignant effusion is usually the same as the tumor of origin, with 17 out of 24 cases ipsilateral in one autopsy series.⁶

CLINICAL FEATURES

The most common symptom associated with a malignant pleural disease is dyspnea, most often from the presence of a pleural effusion (see Chapter 79 for further discussion). Cough is also a symptom that may be due to the presence of a pleural effusion. If the effusion is the cause of these symptoms, both dyspnea and cough can be relieved promptly by thoracentesis. When a thoracentesis fails to relieve these symptoms, tumor infiltration of lung or pleura or another medical condition should be suspected. Chest pain can often be described as a dull ache; this may indicate involvement of the chest wall and sensory neurons of the parietal pleura and chest wall although, with the recognition that sensory fibers lie in the visceral pleura, chest pain may not necessarily mean invasion of the chest wall.⁷ In one series, 34% of patients with a malignant pleural effusion described a dull chest ache, and 24% described pleuritic chest pain.⁸ This differed from those patients with benign causes of their effusions, who were more likely to describe pleuritic chest pain.⁸ Systemic symptoms may include malaise and anorexia.

MALIGNANT PLEURAL EFFUSIONS

Malignant pleural disease can exist without pleural effusion (Video 82-1). In autopsy studies of patients with malignancy, malignant pleural disease was found *without* an effusion in 40%⁶ to 45%⁴ of cases. It is increasingly recognized that malignant cells can reach the pleural space without effusion because lavage of the pleural space before resection of lung cancer in those without effusion can have positive cytologic results (see eFigs. 18-35 and 53-5). In one study of more than 1200 patients with lung cancer without effusion undergoing curative surgical resection, 5.3% had positive pleural cytologic findings on lavage at the time of

thoracotomy before resection.⁹ In fact, positive cytologic results on pleural lavage have poor prognostic significance and may be incorporated into future modifications of the *tumor-node-metastasis* (TNM) staging system; some have advocated using adjuvant chemotherapy in those with positive cytologic findings on preresection pleural lavage.¹⁰ The development of a malignant effusion may depend on the ability of the tumor cells themselves to secrete bioactive mediators or their ability to initiate inflammatory, angiogenic, or fibrinolytic processes in the normal tissues.¹¹

Lung cancer is the most common cause of malignant pleural effusions¹² (see Table 82-1). Lung cancer and breast cancer together account for more than half of all malignant pleural effusions. Of the histologic types of bronchogenic cancers, adenocarcinomas are most frequently associated with malignant pleural effusions, but effusions may be seen with all types.¹³

Breast cancer is the second most common cause of malignant pleural effusions.^{12,14} The time course of development of the effusion from the time of initial diagnosis of breast cancer is usually 2 years but can be up to 20 years. The

effusion usually is ipsilateral to the site of the original tumor (50%) but can also be contralateral (40%) and less commonly bilateral (10%).¹⁵

Lymphoma is the third most common cause in most series¹² but is possibly the most common cause in young adults.¹⁴ Pleural effusions are common in both non-Hodgkin (eFig. 82-1) and Hodgkin lymphoma.¹⁶ In patients with non-Hodgkin lymphoma, approximately 16% will develop malignant effusions, and most will have the effusion at the time of initial diagnosis in association with evidence of disease elsewhere.¹⁷ The high yield of pleural fluid cytologic studies suggests frequent invasion of the pleural space.¹⁸ In some patients with non-Hodgkin lymphoma, chylothorax may also develop; in one analysis of 88 patients with chylothorax, 12.5% were due to lymphoma, all non-Hodgkin lymphoma.¹⁹ In Hodgkin lymphoma, effusions may be caused by hilar or mediastinal lymph node involvement as well as pleural involvement.¹⁶ In one study of 110 patients presenting with Hodgkin lymphoma, effusions were present in 26 (24%); these were equally unilateral or bilateral. The presence of effusion was more common in those with higher-stage disease, extranodal involvement, and bulky mediastinal disease.²⁰

Malignancies probably produce pleural effusions by both increasing the entry of liquid and decreasing the normal exit of liquid (Table 82-2) (see Chapter 79). The entry of liquid can increase by several mechanisms: (1) increased permeability of the pleural vessels by direct invasion of tumor cells, inflammatory and vasoactive cytokines (e.g., *vascular endothelial growth factor* [VEGF]), or injury (e.g., radiation-induced); (2) increased permeability of *pulmonary* vessels by infection, pulmonary embolism, or pulmonary infarct with movement of liquid from lung to pleural space; (3) increased hydrostatic forces due to venous obstruction or hypoproteinemia; and (4) entry of other sources of liquid such as chyle from a disrupted thoracic duct. The exit of liquid from the pleural space can decrease by several mechanisms that would reduce lymphatic drainage: (1) infiltration of parietal pleural lymphatics or mediastinal lymph nodes, (2) lowered pleural pressure due to atelectasis

Table 82-1 Primary Tumors Responsible for Malignant Pleural Effusion

Primary Tumor Site	Total (%)
Lung	37.5
Breast	16.8
Lymphoma	11.5
Gastrointestinal	6.9
Genitourinary	9.4
Other	7.3
Unknown	10.7

A compilation of data from five different reports with a total of 2040 patients. The "other" category includes ovarian carcinoma, sarcomas, uterine and cervical carcinomas, and other carcinomas.

Table 82-2 Physiologic Mechanisms (Neoplastic and Paraneoplastic) by Which Malignancy May Cause Pleural Effusions

Means of Increasing Liquid	Mechanism	Site/Source	Examples
Increased entry	Increased vascular permeability	Pleural vessels	Invasion by tumor Cytokines (e.g., VEGF) Injury (e.g., radiation)
		Pulmonary vessels	Infection (e.g. postobstructive pneumonitis) Cytokines/injury
	Increased vascular hydrostatic gradient	Pleural vessels	Decreased pleural pressure (e.g., atelectasis) Increased venous pressure (e.g., SVC syndrome) Decreased plasma osmotic pressure (e.g., hypoproteinemia)
		Thoracic duct	Chylothorax
Decreased exit	Increased resistance to lymphatic flow	Pleural lymphatics Lymph nodes	Infiltration of parietal pleura Infiltration of mediastinal lymph nodes
	Increased gradient opposing lymphatic flow		Decreased pleural pressure (e.g., atelectasis) Increased venous pressure (e.g., SVC syndrome)

Both an increase in entry and a decrease in exit are likely required to produce a stable pleural effusion. "Paraneoplastic" refers to mechanisms taking place outside the pleural space.

SVC, superior vena cava; VEGF, vascular endothelial growth factor.

Adapted from Broadbush VC: Physiology: fluid and solute exchange in normal physiological states. In Light R, Lee Y, editors: *Textbook of pleural diseases*, ed 2, London, 2008, Hodder Arnold Publishers, pp 43–48.

from bronchial obstruction, or (3) elevated central venous pressure, as from superior vena cava syndrome. We suspect that several factors combine to form a pleural effusion in association with malignancy.²¹ The malignancy alone may be sufficient to tip the balance between the entry and exit of liquid toward accumulation of excess pleural liquid. Alternatively, the malignancy may alter the balance gradually without the development of an overt effusion because lymphatic clearance can handle the excess influx; the advent of another nonmalignant condition, such as heart failure or pneumonia, may then tip the balance and precipitate the appearance of a symptomatic pleural effusion. In these cases, malignancy may contribute to but not be the sole cause of the effusion.²¹ The combination of different processes may explain how malignancy can be associated with transudative effusions, for example, if malignancy interferes with lymphatic clearance and a separate transudative process increases entry of fluid into the pleural space.²² In the same way, malignancy may lead to bilateral effusions; in a prospective study of bilateral effusions, malignancy was found to be a common contributing cause along with other processes.²³

In several animal studies, bioactive molecules involved in angiogenesis and permeability, such as VEGF, have been identified that may play key roles in accumulation of effusions in malignancy.¹¹ An important role of VEGF is supported by the finding that, in patients with malignant effusions due to non-small cell lung cancer, increased pleural fluid VEGF is also associated with poor survival.²⁴ Understanding the mechanisms of effusion formation could lead to new therapeutic approaches such as inhibition of VEGF or the VEGF receptor or interfering with their effects on permeability and angiogenesis. In fact, some clinical responses to anti-VEGF therapy have been observed, and clinical trials are ongoing to determine whether such therapy targeted to VEGF (e.g., bevacizumab or cediranib) can control malignant effusions.^{25,26}

PLEURAL FLUID ANALYSIS

The pleural fluid from malignant effusions is almost always an exudate. The effusion may meet exudative criteria by the *lactate dehydrogenase* (LDH) (either the ratio or the absolute level) only and not by protein criteria.²⁷ Such an observation may indicate that an increased cell turnover and cell lysis is the source of the elevated LDH, whereas an increased vascular permeability needed to produce pleural fluid with increased protein concentration is not present. In some studies, approximately 5% of malignant effusions are found to be transudates.²⁸ In most of these cases, the primary cause of these “malignant” transudative effusions appears to be congestive heart failure or other known cause of a transudate (e.g., superior vena cava syndrome, volume overload), whereas the malignancy has a secondary, contributing role.²⁸ Malignancy could be the primary cause of a transudate if, for example, the malignancy interfered with lymphatic absorption of pleural liquid.²¹ In such cases, one could imagine that normal pleural liquid would accumulate until it formed a transudate. In one interesting case report, a patient with metastatic colon cancer but without other comorbid conditions presented with transudative pleural effusions and negative cytologic results; within 1 month,

the effusions were exudative with positive cytologic findings.²⁹ Biopsy showed parietal pleural lymphatic infiltration, suggesting that the initial transudative effusion was caused by blockage of pleural liquid lymphatic clearance, and that the later exudative effusion was caused by invasion of the pleural space.

The effusion may be grossly bloody; indeed, malignant disease is the most common cause of bloody effusions.³⁰ However, about half of malignant effusions are not bloody in appearance and have pleural fluid red blood cell counts under 10,000 cells/ μ L.³⁰ On cell differential, a predominance of lymphocytes is usual, but a mononuclear or eosinophilic predominance does not exclude the diagnosis. The presence of pleural fluid eosinophilia (>10% eosinophils) has been thought to be unusual in malignant effusion and to argue against the diagnosis.³¹ However, in a more recent study of 460 effusions, 20% of the eosinophilic effusions were found to be malignant; of note, 20% of noneosinophilic effusions were also found to be malignant, showing not only that eosinophilic effusions could be malignant but also that the presence of eosinophilia did not alter the likelihood of malignancy.³² Eosinophilia in many of these situations may be caused by other factors, such as the prior entry of air or blood into the pleural space. In another study in which care was taken to study only the initial thoracentesis to avoid artifacts due to prior entry of air or blood, eosinophilia was present in 12.6% of all effusions tapped, and the presence of eosinophilia did not differentiate malignant from benign causes.³³

The pleural glucose concentration is lower than 60 mg/dL in approximately 20% of malignant pleural effusions.³⁴ Effusions with a low glucose level also tend to have a low pleural pH and may have a larger tumor burden in the pleural space. It would therefore be expected that those patients with a low pleural glucose level or pH would have a shorter survival and a poorer response to pleurodesis, as has been reported.^{35,36} However, other studies have found that pleural fluid pH may not be an accurate predictor of survival^{37,38} and may also fail to predict which patients will respond to a pleurodesis.^{37,39} Therefore neither the pleural fluid pH nor the glucose level should be relied upon for selecting patients for pleurodesis. In fact, for survival, the best predictor may not lie in the pleural space; in one study the best criteria for predicting survival was the Karnofsky score, a scale from 0 to 100 based on results of the history and physical examination.³⁸

Pleural fluid amylase concentration is elevated in 10% of patients with malignant pleural effusions.⁴⁰ However, the origin of the amylase is not the pancreas, as shown by its identification as salivary rather than pancreatic amylase.⁴¹ In one series of consecutive effusions, a very high amylase concentration in malignant pleural fluid (>600 IU/L) was a poor prognostic factor.⁴⁰

RADIOGRAPHIC EVALUATION

The size of malignant effusions may vary greatly. Some may be small, amounting to a few milliliters and only causing blunting of the costophrenic angle, whereas others are large enough to obscure the hemithorax. In fact, malignancy is the most common cause of effusions that are either large, opacifying two thirds of the hemithorax, or

massive, opacifying the entire hemithorax (eFig. 82-2A; see eFig. 82-1A). In one retrospective series of 766 patients, malignancy was found as the cause of 55% of large and massive effusions⁴²; the other causes were pleural empyema and tuberculous effusions. Of these large malignant effusions, most were caused by lung or breast cancer. Interestingly, cytologic examination was no more likely to be positive in these large/massive effusions than in smaller ones (63% yield from large effusions; 53% from small).⁴²

If the effusion is large, it is important to note the position of the mediastinum. It is expected that, in an uncomplicated situation, the mediastinum will be shifted away from a large effusion (see eFig. 82-2A). If the mediastinum is midline, one can suspect one of two things: (1) the pleural pressures are equal on the two sides, implying that significant lung collapse is present and offsetting the increase in pressure expected from the presence of the effusion, or (2) the mediastinum is fixed in position and cannot shift in response to a pressure differential. If the mediastinum is shifted toward the side of the effusion, the pressure is most likely lower on the side of the effusion than on the other side (Video 82-2); in that case, the lung must be unable to expand fully in response to this abnormally low pressure. Because the lung is restricted from expanding or is trapped, due either to main-stem bronchial obstruction or to infiltration by tumor (see eFig. 82-2B), it is unlikely to reinflate with chest tube thoracostomy. In situations where the mediastinum is shifted toward a massive effusion, placement of chest tubes is not recommended. Instead, a bronchoscopy would be a reasonable next step to investigate for bronchial obstruction as a possible reason for the failure of lung expansion.

Computed tomography (CT) has the advantage of providing reasonably detailed information about the pleural surfaces, as well as information about the lung parenchyma, chest wall, and mediastinum. Thus one obtains clues about the identity of the tumor of origin as well as staging information. The typical features found in malignant pleural disease are pleural thickening (>1 cm), irregularity, and nodules (Fig. 82-1 and eFig. 82-3; also see eFigs. 18-35 and 53-5). In a prospective CT study of 40 patients with suspected malignant effusions, these pleural characteristics discriminated well between malignant and benign disease, with a sensitivity for malignancy of 84% and a specificity of 100%.⁴³ In a larger CT study of 211 consecutive patients with effusions, the most specific findings for malignancy were pleural nodules and nodular thickening.⁴⁴ Pleural thickening alone was not as specific and was seen in malignancy as well as empyema. Although the presence of pleural nodules was highly specific, it was not sensitive because only 17% of malignant effusions had associated pleural nodules. Interestingly, half of the patients with malignant effusions had no pleural abnormalities on the CT; other CT findings such as the presence of a pulmonary mass, chest wall involvement, large mediastinal nodes, and hepatic metastases suggested malignancy (Video 82-3).⁴⁴ Even minimal pleural effusions may represent malignant involvement; in patients with lung cancer, a minimal (<10 mm thick) effusion on CT has been shown to be a poor prognostic factor; these minimal effusions were thought to indicate early malignant involvement of the pleural space or of the mediastinal lymph nodes.⁴⁵

Figure 82-1 Metastatic adenocarcinoma. Axial contrast-enhanced chest CT shows right pleural effusion associated with enhancing nodular masses (arrows) emanating from the parietal pleura, later shown to be metastatic adenocarcinoma.

Magnetic resonance imaging (MRI) is not advocated for routine evaluation of malignant effusions. However, its excellent soft-tissue contrast may be useful for detailed evaluation of tumor invasion.⁴⁶ It may be particularly useful in evaluating the chest wall and pleura in the apices of the hemithoraces.

Positron emission tomography with ¹⁸F-fluorodeoxyglucose (PET) can be very useful for differentiating benign pleural abnormalities from malignancy⁴⁷ and provides useful information for staging in cases of documented malignancy (see eFig. 53-4). However, it may not always be able to differentiate pleural malignancy from benign pleural inflammation, such as that due to talc pleurodesis⁴⁸ (Fig. 82-2). In a patient with a history of talc pleurodesis, PET/CT can allow correlation of the increased uptake with areas of increased attenuation characteristic of talc deposits.⁴⁹

DIAGNOSIS

Cytologic examination is reportedly diagnostic in approximately 60% of patients,⁵⁰ but the diagnostic yield varies with the type of tumor, extent of tumor involvement of the pleural space, and the skill and experience of the cytologist (see Chapter 79). Cytologic results are more likely to be positive in adenocarcinoma than in squamous cell lung cancer, for example, perhaps because adenocarcinoma is more often located peripherally and has a greater tendency to invade the pleural space.³⁰ Interestingly, cytologic yield does not vary greatly with the size of the effusion; as mentioned, in one study, cytologic results were positive as often in large or massive effusions (63%) as in small or moderate-size effusions (53%).⁴²

Immunohistochemical staining of cell blocks can be quite useful for diagnosis. Certain markers such as thyroid transcription factor 1 have a high specificity for a lung primary tumor, whereas GATA3 has been proposed as a sensitive and specific immunostain for breast cancer.⁵¹

Figure 82-2 Increased PET activity at site of talc pleurodesis. **A**, A PET/CT scan obtained in a patient with a prior talc pleurodesis for recurrent pneumothorax shows increased pleural uptake (arrows). **B**, The axial chest CT image confirms that the area of increased PET uptake corresponds to an area of high attenuation characteristic of talc deposits.

Cytologic specimens can be used for sequencing for mutations of *epidermal growth factor receptor* (EGFR),⁵² and, with highly sensitive sequencing such as next-generation sequencing, such markers may be detected even when cytologic examination reveals a low percentage or even no malignant cells.⁵³

Biopsy may be necessary when cytologic examination is negative or indeterminate. In the past, closed (or “blind”) pleural biopsy was performed as a next step in cases where cytologic results were negative. However, the patchy involvement of the parietal pleura by malignancy appears to make closed pleural biopsy a “hit-or-miss” technique, and, not surprisingly, image-directed biopsies have been shown to be more accurate. In one randomized study comparing CT-guided biopsy with closed pleural biopsy using an Abrams needle, CT-guided biopsy was significantly more sensitive (87% versus 47%) with a better negative predictive value (80% versus 44%).⁵⁴ Thoracoscopy is a well-tolerated procedure that permits excellent visualization of the entire pleural surface (see Chapter 24 and eFig. 53-5B). Directed biopsies of suspicious areas lead to a correct identification of metastatic pleural disease in nearly 100% of cases.⁵⁵ This technique has additional advantages, including the ability to provide large biopsy specimens for immunohistochemical and genetic analysis for molecular markers (e.g., EGFR) if needed, to provide information about the gross appearance of tumor, to provide information for staging, to lyse adhesions, and to drain the pleural space for talc pleurodesis. It is worth remembering that metastatic disease may be diagnosed by fine-needle aspirates of abnormal lymph nodes in the cervical, supraclavicular, or other regions or by biopsies of mediastinal nodes guided by endoscopic or endobronchial ultrasonography, bypassing invasive tests directed at the pleural space.

Molecular markers for malignancy may be identified as the molecular biology of cancer is better understood. Biomarkers in pleural fluid would potentially assist the cytologic diagnosis (see Chapter 79). Unfortunately, biomarkers have had indeterminate sensitivity and specificity, leading to overlap between malignant and nonmalignant conditions. One approach has been to combine tumor markers to

improve diagnostic yield, although one may predict malignancy as well by using clinical characteristics (time of symptoms more than 1 month, absence of fever, serosanguineous fluid, and chest CT findings of malignancy).⁵⁶ For mesothelioma, detecting the molecule mesothelin, a product of mesothelial cells, may have diagnostic utility in certain circumstances (see “[Mesothelioma](#)” section, later). Interestingly however, pleural liquid mesothelin levels are elevated in many patients with malignant effusions other than mesothelioma, whereas the mesothelin level is not elevated in benign effusions. Thus a high mesothelin level is strongly suggestive of the presence of some sort of malignancy.⁵⁷

The future of diagnosis may include genetic analysis, either for features of malignancy (DNA methylation, mutations, microsatellite, telomerase, aneuploidy) or in the genetic expression fingerprint (microarray) characteristic of tumors.^{58,59} As discussed earlier, genetic testing of pleural cells may lead to the selection of therapy; for example, finding an EGFR mutation in malignant pleural cells may predict response to appropriate EGFR tyrosine kinase inhibitors, such as erlotinib or gefitinib.^{52,53,60} High-throughput sequencing technology, a by-product of the Human Genome Project, enables rapid sequencing of either the whole genome or the small percentage of the genome that codes for expressed genes (i.e., the exome). Because all cancers are unique, it is hoped that this might lead to patient-specific markers and therapies (e.g., construction of specific vaccines that “drive” the host immune system to attack that patient’s cancer).⁶¹

THERAPY AND PALLIATION

The therapeutic and palliative approach to malignant pleural effusions is guided by several factors ([Table 82-3](#)). The options are several and of increasing invasiveness. First of all, the clinician should determine whether the effusion is causing either dyspnea or cough, symptoms that can be due to the volume of the effusion and its effect on lung and cardiac function (see Chapter 79). Symptomatic effusions require an effort to control the effusion, usually by obliterating the pleural space or by draining the effusion, either

Table 82-3 Options for Control of Symptomatic Malignant Effusions

Option	Patient Eligibility and Considerations
Chemotherapy	Chemoresponsive tumor
Thoracentesis	Slowly recurring effusion Used for patients with very short life expectancy
Pleurodesis Via chest tube Via thoracoscopy	Lung able to reinflate Can free up lung tacked down by adhesions, obtain biopsies Thoracoscopy must be available
Indwelling tunneled catheter	Good outpatient situation Good for trapped lung
Pleuroperitoneal shunt	Patient able to operate pump Good for trapped lung Excellent for chylothorax
Pleurectomy Via thoracoscopy Via thoracotomy	When other less invasive options have failed Good patient status and life expectancy

internally or externally. Important issues that help the clinician decide on the approach are the ability of the lung to reinflate fully, the clinical status of the patient, and the availability of approaches such as thoracoscopy. The overall goal is to provide the greatest relief of symptoms using the least invasive, least morbid, and least expensive therapy. Management issues mainly focusing on palliation have been addressed in guidelines from the European Respiratory Society/American Thoracic Society and the British Thoracic Society.^{12,62,63}

Systemic therapy with chemotherapy may be considered, as dictated by the primary malignancy. Malignant pleural effusions that may respond to chemotherapy include those due to breast cancer, small cell lung cancer, and lymphoma.^{15,64,65} Radiation therapy may be useful for treatment of the primary tumor or to treat local areas of chest wall invasion but is limited by the radiosensitive organs adjacent to the pleura, such as the lung and heart. As stated previously, the most common and most debilitating symptom caused by malignant effusions is dyspnea, and control of dyspnea can often be the primary focus of palliative therapy.

Repeated thoracentesis to remove a symptomatic effusion may be used in those unusual circumstances when the fluid reaccumulates slowly and the patient prefers this approach. Nonetheless, most malignant effusions recur rapidly and would need frequent drainage, making this approach useful in only a few cases, such as in a patient with a very short life expectancy.

Chemical pleurodesis can be considered when the lung can reinflate so it comes in contact with the parietal pleura. Even if reinflation is incomplete, as long as the lung can cover a large part of the parietal pleura, pleurodesis may still be effective at preventing the recurrence of large symptomatic effusions and can be considered.⁶³ Pleurodesis with talc is successful in most (70% to 100%) cases⁶⁶ and is more effective than pleurodesis with other agents, including tetracycline and bleomycin.^{62,66} Talc pleurodesis can be painful

and, in a small percentage of patients, can lead to pulmonary edema and acute respiratory failure.¹ Evidence suggests that the smaller talc particles (<10 µm) can exit the pleural space and distribute systemically; in a randomized study, pleurodesis with graded talc (with most particles less than 10 µm removed) was associated with fewer complications than a mixed talc that included small particles.⁶⁷ Alternative sclerosing agents have been investigated, but currently talc is the preferred agent. Nonetheless, there is significant variability in the practice of pleurodesis, as shown in a survey of pulmonologists in five countries.⁶⁸ Other agents include tetracycline, bleomycin, iodopovidone, nitrogen mustard, *Corynebacterium parvum*, and silver nitrate.⁶⁶

Talc can be delivered to the pleural space by instillation as a slurry through a chest tube or by insufflation as a powder (poudrage) during thoracoscopy. Talc slurry can be given via small or large chest tubes, without rotation of the patient. Prospective trials have shown no benefit of standard large-bore tube over small-bore tubes (12 French) for pleurodesis, although talc was used in a minority of these patients,⁶⁹ and no benefit from rotation of patients as determined by instillation of radiolabeled talc and by outcome.⁷⁰ In outpatients, instillation of talc slurry through small-bore catheters followed by removal of chest tubes in 24 hours has shown promise.⁷¹ Talc slurry and talc poudrage have been compared in a prospective, randomized trial and have been found to be similar in efficacy; 71% of patients had a successful 30-day outcome following talc slurry and 78% following poudrage.⁷² Interestingly, for the subgroup of patients with breast or lung cancer, poudrage may have been better than slurry (82% success with poudrage versus 67% with slurry).⁷² Thoracoscopy or video-assisted thoracic surgery also has the ability to drain the pleural space completely at the time of talc poudrage and lyse adhesions, which may allow more success in selected patients.

Chronic indwelling tunneled catheters have been shown to be effective alternatives to chemical pleurodesis, even leading to a symphysis and removal of catheters in many patients. The catheter is inserted under local anesthesia, and the patient drains the effusion via a daily or every-other-day protocol as an outpatient. This approach may be the only alternative when pleurodesis is not possible, as, for example, when the lung cannot reexpand. It has now been recognized that not only can the indwelling catheters control symptoms but, in many cases, they can induce a symphysis, allowing the tube to be removed without recurrence of the effusion. In a review of 263 patients with malignant pleural effusions treated with indwelling tunneled pleural catheters until drainage was less than 50 mL/day, the catheters could be removed in 58% of patients.⁷³ The average indwelling time for the catheter overall was 29 days. The success of the catheter alone was greater in those with breast and gynecologic tumors (70% to 72%), those without a history of chest wall irradiation, those with positive cytologic results, and those with complete reexpansion of the underlying lung.⁷³ An added benefit of this outpatient approach is a reduction in hospitalization time, a particularly attractive feature for a palliative procedure. In the first randomized controlled trial comparing the indwelling catheter versus talc pleurodesis, 106 patients with malignant pleural effusion were treated with an indwelling

pleural catheter inserted as an outpatient procedure or talc slurry via a chest tube as an inpatient procedure.⁷⁴ There was not much difference between the approaches: both relieved dyspnea and had a similar quality of life. More patients in the talc group underwent further pleural procedures (22% versus 6%), and more patients in the catheter group experienced adverse events. Nonetheless, the near equivalence of outcomes indicated that patient preference might guide treatment choice.⁷⁴ A combination of techniques can also be used; in a pilot study, patients with malignant pleural effusions underwent thoracoscopy with talc poudrage and placement of a tunneled indwelling pleural catheter.⁷⁵ For the 30 patients, the pleurodesis was effective in 92% and the catheter could be removed in less than 8 days. Such combinations of approaches could potentially enhance efficacy without increasing hospital stay or adverse events.

Pleuroperitoneal shunting is another alternative for palliation when the lung cannot reexpand or pleurodesis is unsuccessful but is reserved primarily for patients with chylous effusions. It can be considered as a temporary measure while other treatments for the malignancy are initiated. Although it is a more invasive procedure, the pleuroperitoneal shunt allows the redirection of chyle into the abdomen, where it can presumably be absorbed via different routes, and thus minimizes depletion of protein and lymphocytes. Improvement in dyspnea is achieved in most patients (95%).⁷⁶ Of note, the external pump chamber must be manually compressed several times each day to move the pleural fluid into the peritoneal space.

Pleurectomy via thoracotomy can achieve a pleural symphysis. However, with the advent of effective alternatives such as pleurodesis and indwelling pleural catheters, pleurectomy cannot be recommended.

PROGNOSIS

The overall prognosis is poor for most patients with malignant pleural effusions. In an analysis of several studies with a total of over 400 patients, the median survival was 4.0 months.² The survival varied by tumor of origin; patients with malignant effusions from lung cancer had a median survival of 3.0 months, whereas those with pleural effusions from cancer of the breast had 5.0 months, from mesothelioma 6.0 months, and from lymphoma 9.0 months. When used to predict survival for any individual patient, pleural fluid pH or glucose level is not sufficiently robust.² One of the strongest predictors appears to be the Karnofsky performance scale; in a prospective trial of 85 consecutive patients with malignant pleural effusions referred for thoracoscopic pleurodesis, those with a Karnofsky score above 70 had a median survival of 13.2 months, whereas those with a score below 30 had a median survival of 1.1 months.³⁸ Interestingly, in this study, when compared to other measures such as pleural fluid pH, glucose level, or extent of carcinomatous involvement of the pleural surface, performance scoring was the only significant predictor of survival.

The life expectancy of patients with lung cancer and malignant pleural effusion has affected the revised staging classification of malignant pleural effusions⁷⁷ (see Chapter 53). In the sixth edition of the TNM classification, effective

since 1997, malignancy of the pleural space was considered a T4 lesion, with a similar prognosis as other invasive lesions, and patients were staged as IIIB. However, in a comprehensive reassessment of staging and its effect on survival, patients with malignant pleural effusions were found to have a poorer prognosis than other T4M0 patients (8 months versus 13 months) and to be more similar to patients with metastatic disease to the other lung (10 months).⁷⁷ In the revised staging system, pleural malignancy (malignant effusions or pleural nodular malignancy) is considered along with contralateral lung nodules as intrathoracic metastatic disease (M1a). Intrathoracic metastatic disease (M1a) is classified separately from extrathoracic metastatic disease (M1b) because of a somewhat better prognosis.⁷⁷

MESOTHELIOMA

INCIDENCE AND ETIOLOGY

Malignant pleural mesothelioma is uncommon but can no longer be considered rare with almost 3000 cases per year diagnosed in the United States alone. The number of cases is anticipated to continue to increase in the United States and Western Europe until approximately 2020⁷⁸ because of the increase in occupational exposures to asbestos and asbestos-containing products after World War II. During the heyday of excitement about asbestos, asbestos was viewed as a modern breakthrough because it was cheap and yet provided good insulation and fire resistance and was able to be woven or molded into thousands of different products. Asbestos was even used in such products as toothpaste⁷⁹ and cigarette filters!⁸⁰ Unfortunately, after extensive use in industry and in building materials, asbestos fibers were discovered to be harmful. It appears that their mechanisms of action are multiple⁸¹ (see later).

After 2020, the number of cases is anticipated to plateau and then gradually decline in Western countries because of the reduction in occupational exposures caused by restrictions on asbestos use, worker protection, and asbestos abatement efforts that were instituted from the mid-1970s to 1990s. In those industrialized countries where the control of asbestos was delayed by several decades, as in Japan, the “epidemic” of mesothelioma may also be delayed by several decades. Unfortunately, asbestos continues to be mined, and its use is actually increasing to high levels in many developing countries, with little environmental controls, raising the specter of a fresh new era of asbestos-related diseases.⁸² Globally there is a great disparity in asbestos use, with some countries adopting “asbestos bans” and others using asbestos without regulation. Interestingly, the United States does not have a ban, although asbestos use has fallen to less than 1% of its historical peak.⁸³ In countries with unregulated use of asbestos, the incidence of malignant mesothelioma is expected to reach high levels in the future. Asbestos-induced lung cancer will also be expected to increase because of the multiplicative effects of asbestos inhalation (including chrysotile) and cigarette smoking⁸⁴ (see Chapter 52).

Those with significant asbestos exposure and increased rates of mesotheliomas include workers in the asbestos

industry, insulators, pipe fitters, shipyard workers, brake mechanics, railroad workers, construction workers, carpenters, plumbers, electricians, painters, nonasbestos miners, welders, machinists, manufacturers of mineral products, and workers who perform maintenance and repair in buildings with asbestos insulation.⁸⁵ In addition, it is not uncommon to see women with mesothelioma whose only clear asbestos exposure was from exposure to their spouses' contaminated clothing. Children who have been incidentally exposed can develop mesothelioma in early adult life.

Besides those who mined or milled asbestos (the "first wave") and those who worked with asbestos in industry (the "second wave"), there is now a third wave of those exposed inadvertently to asbestos during short-term or low-level exposure in the home or workplace.⁸⁶ The most common inadvertent exposure is thought to be during home renovations, a source that may be causing an increasing incidence of mesothelioma.⁸⁶ Incidence may also rise because of population exposures such as from the dust that settled after the collapse of the World Trade Center.⁸⁷ In addition, the use of nanoparticles and nanotubes raises concerns for unforeseen toxic effects analogous to those of asbestos, although this has not been proven.^{88,89}

Other causes of mesothelioma have been postulated. There has been a great deal of controversy as to whether a simian virus (SV40) that contaminated the polio vaccine administered from 1955 through 1961 may be contributing to the development of mesotheliomas in the United States and other countries. SV40 is an intriguing candidate because it can immortalize cells by binding and inactivating both the retinoblastoma protein and p53, key control steps for proliferation and apoptosis, respectively. In a review of 15 studies, mesothelioma tissues were 17 times more likely to have evidence of SV40 compared to control tissues.⁹⁰ In cell and animal studies, SV40 may cooperate with asbestos in inducing damage and generating mesothelioma.⁹¹ However, in humans, a causal relationship has not been established, and epidemiologic studies to date have not shown an increase in the incidence of mesotheliomas in populations exposed to this virus.^{92,93} Further complicating the analysis is the recognition that the presence of SV40 DNA sequences alone does not prove its role in tumor development; to be oncogenic, viral proteins must be expressed and impair the function of cell proteins necessary for normal cell function. At this time, SV40 is still a subject of intense discussion, more as a possible co-carcinogen with asbestos than as a primary cause of mesothelioma. See arguments addressing the evidence for⁹⁴ and against⁹⁵ SV40 as a cause of mesothelioma.

Cigarette smoking is not associated with an increased incidence of mesotheliomas.⁹⁶ Silica or man-made vitreous fibers (rock/slag wool and fiberglass) have not been found to be associated with occupational mesotheliomas.^{97,98} Excess cases of mesotheliomas have been identified in oil refinery workers; this risk was once thought to be due to exposure to petroleum oil and its products but is now attributed to occupational asbestos exposure.⁹⁹ Ionizing radiation may be a cause or may contribute to development of mesothelioma; a small increased risk for mesothelioma has been described in patients exposed to the contrast medium

Thorotrast (containing thorium dioxide), to radiation therapy, and to low-level radiation as atomic energy workers.¹⁰⁰

Environmental asbestos exposures are also associated with the development of mesothelioma. Low-dose exposure in large populations may produce only "background" levels of asbestos in lung tissue but, because of the large number of individuals exposed in that way, may lead to an increase in the number of mesothelioma cases (similar to widespread exposure to sunlight and melanoma development). In Turkey an extraordinarily high incidence of mesothelioma is found in certain villages in central Turkey with exposure to erionite dust, a nonasbestos crystalline fibrous form of the mineral zeolite.¹⁰² Erionite is now recognized to be in many locations, including in the western United States, and may be a future hazard due to the use of erionite-containing gravels on some roadways.^{102,103}

Finally, chronic inflammation of the pleura as seen in familial Mediterranean fever has been postulated to cause mesothelioma. At least four cases of mesothelioma have been reported in patients with this disease, presumably due to recurrent serositis.¹⁰⁴ Asbestos may still be an underlying cause or contributing factor in patients without a clear occupational exposure given that fiber burden studies suggest that most urban dwellers have some asbestos fibers in their lungs.¹⁰⁵

Although millions of workers have been exposed to significant amounts of asbestos, only a few develop mesothelioma, making it likely that there are genetic factors that increase susceptibility. Supporting the notion of genetic susceptibility is the identification of multiple clusters of this disease in families,¹⁰⁶ although clusters may also be explained by common environmental exposure to asbestos. Nonetheless, in the Cappadocian region of Turkey, where exposure to erionite is widespread, the susceptibility to mesothelioma appears to be inherited in an autosomal dominant pattern.¹⁰⁷ Mesothelioma susceptibility genes have been reported using genome-wide association studies.¹⁰⁸ Some familial clustering of mesothelioma has been found to be due to a germline *BAP1* (BRCA1-associated protein-1) mutation, a discovery that links predisposition to mesothelioma with predisposition to other tumors such as uveal melanoma, although this familial feature is uncommon in mesothelioma.¹⁰⁹

GENETIC CHARACTERISTICS

The three tumor suppressor genes most frequently implicated in mesothelioma are *CDKN2A* (or *P16INK4A-P14ARF*), the *neurofibromatosis type 2* (*NF2*) gene, and the *BAP1* ubiquitination-related gene.¹¹⁰ (For discussion of genetic abnormalities in lung cancer, see Chapter 51.) Studies of cytogenetics and loss of heterozygosity show consistent losses of chromosomal regions, suggesting that these regions may contain genes for key tumor suppressors. Losses are consistently found in regions 1p, 3p, 6q, 9p, 13q, 15q, and 22q. Oncogenes or growth-promoting genes suspected to play a role in mesothelioma include those coding for c-Myc and for growth factors or growth factor receptors (e.g., platelet-derived growth factor, EGFR). Gene expression profiling and high-throughput, next-generation sequencing

are beginning to be explored and will likely provide additional insights into genetic abnormalities critical for mesothelioma; genetic discoveries may also provide prognostic information, help with diagnosis, guide therapy, and suggest future therapeutic approaches.¹¹¹⁻¹¹³

Action of Fibers at the Pleura

The long latency period between exposure to asbestos and development of mesothelioma suggests that multiple genetic abnormalities are required. Unlike the situation for bronchogenic carcinoma, where the natural history can be studied by repeatedly accessing the bronchial epithelium, the pleural space is not easily sampled, making the natural history of mesothelioma more opaque.¹¹⁴ Many pleural diseases can be caused by asbestos fibers, including plaques, rounded atelectasis, fibrosis, and benign asbestos pleurisy.¹¹⁵ Of these, mesothelioma has the longest latency.

Due to their long thin shape, asbestos fibers are inhaled deep into the lung and translocate from the lung to the pleural space and accumulate at the parietal pleura, where they can interact with mesothelial cells over decades.¹¹⁴ The fibers have been found to accumulate at particular spots, where carbon also accumulates, seen at thoracoscopy as “black spots”; these spots probably correspond to sites of lymphatic clearance of pleural fluid and cells.¹¹⁶ The fibers are ingested by macrophages, inducing a chronic inflammation within the lung and pleura. The fibers may also be internalized by mesothelial cells, where they can interfere with chromosome segregation, leading to chromosome damage, and generate reactive oxygen species via their iron content, leading to oxidant injury to DNA.¹¹⁷ From cell and animal studies, it appears that asbestos can injure the chromosomes both by generating reactive oxygen species that damage DNA and by mechanical breakage of chromosomes.¹¹⁸ In the process, the cells develop unregulated proliferation and an increased resistance to apoptosis.¹¹⁹ The combination of chronic inflammation and chromosomal and DNA damage may explain their potent carcinogenic effect. Loss of key genetic areas containing tumor suppressors may be critical steps in generating mesothelioma. If SV40 contributes to this process, it may be by binding and inactivating key regulators of cell growth and survival, retinoblastoma and p53 proteins.

CLINICAL FEATURES

The mean age at presentation is 60 years because of the long latency (usually 30 to 40 years) from the time of first exposure to asbestos to the development of clinically evident disease.⁷⁸ The incidence is higher in men, presumably because more men have worked in asbestos-related trades.

Symptoms and physical findings are generally not specific for the disease. Most patients present with nonpleuritic chest pain or dyspnea.¹²⁰ Compared to that of metastatic pleural diseases, the pain from mesothelioma can be severe, aching, and often very difficult to control. Less common complaints are cough, fevers, chills, sweats, and fatigue. Fatigue, cachexia, and pain are common in advanced disease. Physical examination is usually remarkable only for signs related to the presence of a pleural effusion or

mass. Later in the course of disease, one can often appreciate volume loss and decreased mobility of the chest wall on the side of the primary tumor. Occasionally the tumor may extend directly into the chest wall and be detected as a tender or nontender chest wall mass.

Laboratory findings are also nonspecific and include anemia and thrombocytosis. Thrombocytosis (platelets > 400,000/ μ L) can be seen in 40% of patients, may be due to production by the tumor of interleukin-6, and augurs a poor prognosis.^{121,122} Measurement of mesothelin in serum shows promise for the diagnosis of mesothelioma and for monitoring of disease progression.¹²³

RADIOGRAPHIC EVALUATION

The most common findings on chest radiograph are a moderate to large unilateral pleural effusion or unilateral pleural thickening (nodular or smooth)¹²⁰ (Fig. 82-3 and Video 82-4). In a study of 99 patients with malignant mesothelioma, the most common finding on CT was a rindlike extension of tumor on the pleural surfaces (eFig. 82-4) (70%).¹²⁴ Other findings included circumferential lung encasement by multiple nodules (eFig. 82-5) (28%), pleural thickening with an irregular margin between the lung and pleura (26%), and pleural thickening with pleural-based nodules (20%). Invasion of soft tissues and the chest wall (eFig. 82-6) with rib destruction may also be seen (Video 82-5). As the disease progresses and the lung becomes more encased with tumor, there is often volume loss with a shift of the mediastinum toward the side of the primary tumor (see Fig. 82-3). Signs of lymphatic metastasis may be seen (eFig. 82-7) but are more commonly evident late in the course of disease. Further tumor progression may lead to invasion into the contralateral chest. It is important to note that pleural plaques are often not visible; only 28% have radiographically apparent plaques (eFig. 82-8).¹²⁵ Large mediastinal lymph nodes are more consistent with metastatic disease than with mesothelioma. Mediastinal adenopathy on chest radiographs or CT as the initial

Figure 82-3 Mesothelioma. Axial chest CT scan shows diffuse right pleural thickening (arrows) associated with marked volume loss in the right thorax. Note the presence of mediastinal pleural involvement (arrowhead).

presentation of mesothelioma has been reported but is exceedingly rare,¹²⁶ although PET scanning often identifies active nodes that are normal in size and shape on imaging.¹²⁷ Radiographic features that favor the diagnosis of malignant mesothelioma over metastatic pleural disease were found by multivariate analysis to include rindlike pleural involvement, mediastinal pleural involvement, and pleural thickness more than 1 cm.¹²⁴

Some clinicians prefer MRI (eFig. 82-9) over CT for staging and preoperative evaluation because, as reported in one study, MRI may demonstrate extent of disease and in particular chest wall and diaphragmatic invasion better than CT¹²⁸ (Fig. 82-4). However, this has not yet been shown to confer an important clinical advantage. In an earlier study, Heelan and coworkers¹²⁹ also found MRI superior in detection of tissue invasion in these areas; nonetheless, they found no improvement in staging and no alteration in therapy due to its use.

PET and particularly PET/CT shows promise as a tool to differentiate benign from malignant disease and as an adjunctive tool for staging (Fig. 82-5; see eFigs. 82-4E-H and 82-5C). In a comparison of different diagnostic imaging techniques in patients with mesothelioma who then underwent surgery, PET/CT was more accurate than PET, CT, or MRI alone.¹³⁰ It is hoped that functional assessment by PET may also be useful for stratifying patients by prognosis¹³¹ and for monitoring response to therapy.¹³²

In patients being considered for an extensive debulking procedure such as extrapleural pneumonectomy (in which the entire pleura is removed along with ipsilateral pericardium, diaphragm, and lung), every effort should be made to define the extent of disease, in particular to exclude patients with unsuspected extension beyond the pleura. A combination of the imaging techniques may be necessary for determining the best approach to the patient.¹³³ Imaging alone may be insufficient; for patients being evaluated for surgery, even for those with negative imaging, the preoperative workup will often include additional studies such as endoscopic ultrasonography with biopsy of suspicious nodes or thoracoscopic visualization of the contralateral

pleura or peritoneum (see “Surgical Therapy” section, later).¹³⁴

DIAGNOSIS

The role of pleural fluid cytologic examination in establishing a diagnosis is controversial, with some groups demonstrating a high level of diagnostic specificity and others demanding tissue histopathologic analysis.¹³⁵⁻¹³⁷ Patterns of gene expression by microarray in cytologic samples may also help with diagnosis.¹³⁸ The only serum biomarker that is clinically useful is serum mesothelin, which, in the serum,

Figure 82-4 Mesothelioma. Magnetic resonance imaging of the same patient as in Figure 82-3 with malignant mesothelioma showing invasion across the diaphragm by tumor (arrow).

Figure 82-5 Malignant pleural mesothelioma: PET/CT appearance. **A**, Axial enhanced chest CT shows extensive, nearly circumferential right pleural thickening associated with volume loss affecting the right thorax. **B**, PET, and **(C)** fused PET/CT images show extensive metabolic activity within the tumor, correlating with the location of the pleural thickening seen at CT. (Courtesy Michael Gotway, MD.)

has a high specificity (over 90%) but only a 50% sensitivity for the diagnosis.¹³⁹ Other biomarkers such as hyaluronic acid, osteopontin, and fibulin 3 lack specificity.^{139a} The high specificity of mesothelin means that a patient with an undiagnosed effusion and an elevated serum mesothelin level has a high likelihood of having mesothelioma. Mesothelin biomarker levels in pleural fluid may also be useful in diagnosis.¹⁴⁰

Closed pleural biopsy often misses malignant tissue, though the yield may be improved using CT or ultrasonographic guidance. In one study in which patients were randomly assigned to closed pleural biopsy or CT-guided biopsy, mesothelioma was diagnosed by closed pleural biopsy with a sensitivity of 55% (6/11) and by CT-guided biopsy with a sensitivity of 89% (8/9); although the difference was not significant because of small numbers, a similar diagnostic advantage of CT-guided biopsy was found for other pleural malignancies.⁵⁴ With current immunohistochemical stains, mesothelioma can usually, though not always, be differentiated from metastatic adenocarcinoma. It is often harder to differentiate mesothelioma from the benign mesothelial cell hyperplasias that often accompany inflammatory processes in the pleura. In uncertain cases, surgical biopsy is required to establish a definitive diagnosis. A surgical biopsy not only provides larger specimens for immunohistochemistry and perhaps electron microscopy, but also provides critical information about the biologic behavior of the tumor. The behavior of mesotheliomas is unique in that they usually start on the parietal pleural surface with multiple colonies of cells that coalesce and spread to the visceral pleura. Distant metastases are generally a very late finding. In contrast, metastatic adenocarcinomas are usually more prominent on the visceral pleural surface and are often associated with distant metastasis.

The preferred technique for surgical biopsy is thoracoscopic biopsy (see Chapter 24). Not only does thoracoscopy have the advantage of obtaining large samples, but also it permits the drainage of effusions and the freeing up of a trapped lung.¹⁴¹ In addition, if the lung is not trapped, talc can be insufflated at the end of the procedure to achieve a pleurodesis. The location of the insertion site of the thoracoscope is an important consideration if tumor debulking is attempted in the future because of the tendency of mesotheliomas to seed biopsy and chest tube sites.¹³⁵ Misdiagnosis with thoracoscopy has rarely been reported and, in those cases, was thought to be due to adhesions preventing access to the primary tumor.¹⁴² If thoracoscopy cannot be performed, an incisional biopsy has an equally high diagnostic yield.

Talc insufflation has been reported to have a greater than 95% success rate of preventing recurrent pleural effusion in this setting¹⁴³ (see [Video 24-5](#)). Talc pleurodesis does not apparently interfere with later attempts at surgical debulking. However, talc pleurodesis does interfere with any intrapleural therapy that might be considered, as in clinical trials of gene therapy, so this should be considered before pursuing pleurodesis. Talc pleurodesis can also confound interpretation of PET, which can show increased activity in areas of talc deposition for long periods of time following pleurodesis⁴⁸ (see [Fig. 82-2](#)). In such cases, PET/CT may be helpful by localizing the increased activity on PET to areas of increased attenuation on CT due to talc.⁴⁸

PATHOLOGIC FEATURES

The dilemma for the pathologist can be in differentiating mesothelioma both from metastatic adenocarcinoma and from nonmalignant reactive mesothelium. Use of a panel of immunohistochemical stains is now standard for the diagnosis of mesothelioma, including antibodies that stain positively for mesothelioma (calretinin, cytokeratin 5/6, WT1) and those that stain negatively (e.g., adenocarcinoma-specific stains such as CEA, MOC-31, B72.3, Ber-EP4).^{144,145} The actual panel of antibodies used may depend on the differential diagnosis under consideration.¹⁴⁵ Ultrastructural features seen with electron microscopy that are typical of mesothelioma include cytoplasmic tonofilaments and long, sinuous, branching microvilli; in contrast, the microvilli of adenocarcinomas are relatively short, wide, and straight.¹⁴⁶ Nowadays electron microscopy is rarely if ever used because immunohistochemistry is faster, cheaper, and more useful; if needed, electron microscopy to detect microvilli may also be performed on formalin-fixed tissue from paraffin blocks.¹⁴⁵ Although a variety of immunohistochemical stains have been used to differentiate mesothelioma from adenocarcinoma, none is specific, especially with poorly differentiated tumors. Sarcomatous and biphasic mesothelioma raise special issues, usually in differentiating from other sarcomatous tumors.¹⁴⁴

PROGNOSIS AND STAGING

The median survival for patients with malignant mesothelioma is between 9 and 12 months from the time of diagnosis.^{147,167} Regardless of therapy, patients with the epithelial cell type do best, and those with the sarcomatous cell type the worst, with mixed or biphasic usually falling between the two other types.¹⁴⁷ In two separate studies, age, male gender, performance status, leukocytosis, and presence of chest pain were associated with a worse prognosis.^{121,148}

Staging is an issue for those patients in whom surgery is contemplated and continues to be controversial. Before the proposal of a TNM-based staging system by the *International Mesothelioma Interest Group* (IMIG),¹⁴⁹ there had been at least six other systems proposed for staging of mesotheliomas. None of the six was clearly shown to predict survival, including the most widely used Butchart staging system.¹⁵⁰ The IMIG TNM-based staging system is organized in a manner similar to the system currently in use for non-small cell carcinoma of the lung ([Table 82-4](#)). Further surgical studies at Memorial Sloan Kettering supported the prognostic value of this system.^{151,152} For example, patients with stage I disease had a median survival of 30 months, and those with stage IV had a median survival of 8 months.¹⁵² However, the Brigham group found it less useful for determination of surgical resectability and have proposed yet another staging system that is also widely used¹⁵³ ([Table 82-5](#)). It should be noted that this staging system requires resection to determine the involvement of surgical margins, limiting its applicability mostly to postsurgical staging. A new staging system is being devised by the *International Association for the Study of Lung Cancer* (IASLC) and the IMIG, which have assembled a large, multicenter, and international database of patients; an initial analysis

Table 82-4 International Mesothelioma Interest Group Staging System for Malignant Pleural Mesothelioma

T1	Tumor limited to ipsilateral parietal pleura
T1a	No involvement of visceral pleura
T1b	Some scattered foci involving visceral pleura
T2	Tumor involving entire ipsilateral pleura, both visceral and parietal Plus, invasion of diaphragmatic muscle Or, confluent involvement of visceral pleura, including the fissures Or, invasion from visceral pleura into pulmonary parenchyma
T3	Tumor locally advanced but potentially resectable
T4	Tumor locally advanced but technically unresectable
NX	Regional nodes cannot be assessed
N0	No lymph node metastasis
N1	Metastasis to ipsilateral bronchopulmonary or hilar lymph nodes
N2	Metastasis to subcarinal or <i>ipsilateral</i> mediastinal nodes
N3	Metastasis to <i>contralateral</i> mediastinal or internal mammary nodes, or to any supraclavicular node
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present
Stage	Description
Stage I	
Ia	T1aN0M0
Ib	T1bN0M0
Stage II	T2N0M0
Stage III	Any T3M0 Any N1M0 Any N2M0
Stage IV	Any T4 Any N3 Any M1

From Rusch V, Group IMI: A proposed new international TNM staging system for malignant pleural mesothelioma. *Chest* 108:1122–1128, 1995.

Table 82-5 The Brigham Staging System for Malignant Pleural Mesothelioma

Stage	Description
Stage I	Completely resectable
Stage II	Positive surgical margins and/or intrapleural adenopathy*
Stage III	Local extension and extrapleural disease
Stage IV	Distant metastasis

*Intrapleural adenopathy is any node present in the resected pleural envelope.

From Sugarbaker DJ, Norberto JJ, Swanson SJ: Surgical staging and work-up of patients with diffuse malignant pleural mesothelioma. *Semin Thorac Cardiovasc Surg* 9:356–360, 1997.

indicates that the staging using the tumor and nodal descriptors effectively describes prognosis.¹⁵⁴

Staging systems may be supplemented by prognostic scoring systems that do not require surgical staging. Prognostic scoring systems proposed by the European Organisa-

tion for Research and Treatment of Cancer and by the Cancer and Leukemia Group B incorporate performance status, histopathology, and other laboratory studies.¹²¹ A change in biomarker levels may be an accurate prognostic feature.¹⁵⁵

APPROACH TO THERAPY

The best therapy for mesothelioma is not known. In part because mesothelioma is unusual and dispersed internationally, there have been fewer randomized, controlled trials than are commonplace for other tumors. Guidelines for therapy have been proposed by the European Respiratory Society,¹⁵⁶ by the Asbestos Diseases Research Institute of Australia,¹⁵⁷ and by the National Comprehensive Cancer Network.¹⁵⁸

Surgical Therapy

The two potential goals of surgical therapy for mesothelioma are palliation of symptoms and debulking of tumor with therapeutic intent. Many believe that therapy should follow the paradigm of treatment developed for ovarian cancer because of the similarities in biologic behavior of the cancer and similar embryologic origin of the cells of the primary tumor.¹⁵⁹ In both diseases, surgical resection alone does not prevent disease recurrence. However, the approach of surgical debulking followed by systemic chemotherapy has shown significant success for the treatment of ovarian cancer. For surgical debulking of mesotheliomas, two surgical approaches are commonly employed, *pleurectomy with decortication* (P/D) or *extrapleural pneumonectomy* (EPP). P/D removes all gross disease from all pleural surfaces and preserves the underlying lung; in recommendations from the IASLC and IMIG, an “extended” P/D is proposed for the situation in which the diaphragm or pericardium is also resected.¹⁶⁰ EPP entails en bloc removal of the lung along with surrounding parietal pleura, pericardium, and diaphragm, with the pericardium and diaphragm then replaced by synthetic grafts. These are all technically challenging procedures and should be performed only by surgeons with extensive experience. EPP is especially difficult and was originally associated with an unacceptably high morbidity of 30%. However, with advances in surgical, anesthetic, and critical care techniques, and more exacting patient selection, experienced centers now report mortality rates of less than 4%, a rate comparable to standard pneumonectomy.¹⁶¹ Both P/D and EPP are accomplished through an extended posterolateral thoracotomy and, as mentioned earlier, previous talc pleurodesis is not a contraindication to either procedure.

Preoperative evaluation of patients considered for surgery includes a thorough assessment of tumor stage, cardiac function, and pulmonary function. Most surgery is confined to those with the epithelial cell morphologic features. If debulking surgery is to be of benefit, it is essential that tumor is at an early stage and confined to one hemithorax. Chest CT and MRI are the usual first steps in staging. MRI is preferred by some centers for assessment of transdiaphragmatic extension of tumor (see Fig. 82-4), and many now request PET or PET/CT as well (see Fig. 82-5 and eFigs. 82-4E–H and 82-5C). Recognition that mediastinal lymph node involvement is a poor prognostic sign has

prompted centers to require either cervical mediastinoscopy, endoscopic ultrasonography, or endobronchial ultrasonography with biopsy of suspicious nodes before EPP. Even with negative findings on imaging studies, some groups perform extensive surgical staging with mediastinoscopy and laparoscopy because mesothelioma often spreads through the diaphragm to the peritoneum.¹³⁴

For patients who successfully complete such extensive screening, a few large series suggest that surgical debulking procedures may provide a survival advantage. In the first studies in which both surgeries were performed, it appeared as if pleurectomy was superior, with better survival than EPP.^{151,162} However, in a follow-up report, the same investigators found that there was no difference in median survival between the two surgical debulking procedures.¹⁵² Both series showed that failure after pleurectomy is more often local, whereas failure after EPP is more often extrathoracic. These results underscore the difficulty in eradicating mesothelioma with surgery alone.

Based on such studies showing that surgery alone is insufficient to cure mesothelioma, Sugarbaker and colleagues¹⁶¹ at the Brigham and Women's Hospital developed a strategy of tumor debulking using EPP followed by chemotherapy and high-dose radiation therapy to destroy residual tumor cells. This strategy was reported to yield a median survival of 19 months and 5-year survival of 15%.¹⁶¹ However, patients with all three positive variables (an epithelial cell type, clean margins after resection, and negative lymph nodes) had a median survival of 51 months and a 5-year survival of 46%. Of note, patients with sarcomatous cell type did especially poorly. These results, although exciting, have been criticized for selection bias. Given the lack of prospective randomized studies comparing surgery with or without adjuvant therapy to medical management or supportive care, the therapeutic or even palliative benefit of surgical debulking followed by chemotherapy and radiation therapy remains unknown. Some critics point out that there are some long-term survivors without treatment and that surgery may actually harm patients without improving survival.¹⁶³ For example, in one unrandomized prospective study, 52 patients receiving surgery and other treatments (chemotherapy or radiation therapy) were compared to 64 patients without treatment. Although the treatments were felt to provide palliation, there was no significant difference in survival between treated and untreated patients.¹⁶⁴ Until randomized studies are performed, the best treatment plan for patients with mesothelioma will remain unknown.

Surgical debulking has been combined with a variety of other cytoreductive approaches to destroy residual tumor cells on the surface of the thoracic cavity, including hyperthermia and photodynamic therapy, without convincing success. At this time, the value of surgical debulking and adjunctive measures such as hyperthermia, photodynamic therapy, chemotherapy, immunotherapy, and radiation therapy is not known. It may be that an approach of debulking followed by some modality to eradicate residual tumor will improve outcome. The issue of radical surgery for mesothelioma has again entered the medical literature.^{165,166} However, until randomized trials are undertaken and a consensus is reached on staging, both of which are difficult to achieve, this will not be known with confidence.

Chemotherapy

There are two main regimens that are used in mesothelioma. The most commonly used now includes the multitargeted antifolate drug pemetrexed with a platinum drug such as cisplatin. The use of this combination was compared to cisplatin alone in a large Phase III study of 456 patients.¹⁶⁷ Response rates were significantly better in the pemetrexed-cisplatin arm than in the cisplatin-alone arm (41.3% versus 16.7%), and survival was significantly better as well (median survival, 12.1 months versus 9.3 months). Importantly, the addition of folic acid and vitamin B₁₂ significantly reduced toxicity without altering survival benefit.¹⁶⁷ The other regimen used commonly is the false nucleotide gemcitabine with a platinum agent. Nearly half of the patients on this doublet regimen noted symptom improvement, 33% had a partial response, and 60% had stable disease; no survival benefit was demonstrated compared to historical controls.¹⁶⁸

Newer Agents under Study

Studies of the molecular biology of mesothelioma and the cellular mechanisms leading to a malignant phenotype have led to the identification of several possible therapeutic targets for treatment of this disease. Some of these are under investigation in clinical trials (see www.clinicaltrials.gov). Monoclonal antibodies labeled with toxins targeted to the protein mesothelin on the surface of mesothelioma cells have produced some major responses in immunotoxin trials.¹⁶⁹

Radiation Therapy

Despite evidence from *in vitro* studies,¹⁷⁰ the clinical experience reported by radiation oncologists suggests that mesothelioma is an especially radioresistant tumor. In addition, radiation of the involved chest is limited by the presence of radiosensitive organs and the extensive nature of the tumor. As a consequence, its use appears limited to adjunctive therapy for patients who have undergone EPP and to palliative treatment of painful chest wall lesions. Prophylactic chest wall irradiation may reduce the incidence of chest wall recurrences at incision sites, but there is no consensus on its use and randomized controlled trials are needed.¹⁷¹ An area of active ongoing research is the role of high-dose hemithorax irradiation after EPP for early-stage disease. In carefully staged patients, this approach has resulted in a marked reduction in local tumor recurrences, although nearly one half of patients subsequently developed isolated distant metastases.¹⁷²

Immunotherapy

It is known that an immune response, although weak, is induced by mesothelioma.¹⁷³ This knowledge has prompted a number of investigators to study different ways of strengthening that response. The intrapleural instillation of cytokines is limited by the short half-life of most cytokines, necessitating repeated injections or continuous infusion via a pleural catheter. In studies reported in the early 1990s, intrapleural interferon- γ twice weekly for 2 months was reported to induce a response rate of 56% in early-stage disease.¹⁷⁴ A continuous intrapleural infusion of interleukin-2 induced a partial response in 4 of 21 patients

and an overall survival of 16 months.¹⁷⁵ In both cases, side effects were minimal and consisted primarily of fever and constitutional symptoms. Studies in animals suggest that interferons have an antiproliferative effect on mesothelioma cells and enhance the cytotoxic effect of cisplatin. The results from these studies led to the development of a Phase II trial of cisplatin-doxorubicin and interferon alpha-2b in advanced malignant mesothelioma.¹⁷⁶ The overall response was modest; however, severe myelosuppression was seen in most patients, limiting the application of this treatment.¹⁷⁶ Patient-specific vaccines have been studied, as have other immunotherapies, and this remains a very active area of research.^{177,178}

Gene Therapy

Gene therapy may be particularly suited to use in mesothelioma because the disease is usually localized to a space that can be reached relatively easily and offers a large surface area for gene transfer.¹⁷⁹ Strategies that have been investigated for the treatment of mesothelioma include mutation compensation, molecular chemotherapy, and genetic immunopotential. Mutation compensation attempts to block or replace abnormally expressed genes. The best example of this in mesothelioma is compensation for the absence of p16 gene expression, a consistent abnormality in mesothelioma. Reexpression of p16 using an adenoviral vector improved survival in a murine model of mesothelioma.¹⁸⁰ Molecular chemotherapy is a technique of genetically modifying cells to make them susceptible to a drug. For example, an adenoviral vector containing the herpes simplex thymidine kinase gene has been injected into the pleural space of patients; the virus is taken up by mesothelial cells, and the herpes simplex thymidine kinase gene product causes the cells to metabolize ganciclovir to a toxic by-product. In humans, such approaches have been limited by patchy viral uptake and the development of immunity to the virus.¹⁸¹ Genetic immunopotential employs the genetic induction of an inflammatory antitumor response.^{182,182a}

Palliative Therapy

Pain is common and often disabling. Invasion of the chest wall can cause localized somatic pain, intercostal nerve invasion or vertebral invasion can cause neuropathic pain, and lung invasion may cause diffuse visceral pain. Opioids, such as liquid morphine plus sustained-release morphine, are the mainstay of pain control. Somatic pain may respond to nonsteroidal anti-inflammatory drugs, and neuropathic pain may benefit from an anticonvulsant such as carbamazepine or valproate sodium. Some patients require procedural pain relief as from intrathecal analgesia or nerve block. Cordotomy, the creation of a lesion in the lateral spinothalamic tract in the anterolateral spinal cord, has been evaluated in a systemic review; although cordotomy appeared to be safe and effective, further study and a national registry were recommended.¹⁸³

Dyspnea and cough are often due to large pleural effusions or from tumor spread. The approach to palliation has been described for malignant pleural effusions earlier in this chapter, and some of these options are applicable to the effusions due to mesothelioma as well (see Table 82-3).

Pleurodesis with talc is an option if a patent pleural space is not needed in the future, as for intrapleural therapy in the setting of a clinical trial. Talc pleurodesis is reasonably effective and a relatively inexpensive agent for this task. As described earlier, it can be administered as a slurry through a chest tube or as a powder during thoracoscopy with equal effect. Regardless, with either technique, the affected lung must be capable of expanding so that the visceral and parietal pleura are in contact. Placement of a tunneled pleural catheter for chronic pleural drainage is another option for these patients, as described for malignant pleural effusions earlier.

Psychosocial care is also very important in palliation given the fear, anger, and suffering associated with the disease.^{184,185} When patients exposed to asbestos are eligible for compensation, physicians can provide that information to patients; in a study in the United States, physicians often missed the opportunity to inform their patients about compensation and legal redress.¹⁸⁶

CHEMOPREVENTION AND SCREENING

The existence of populations with known exposure to asbestos suggests that an effective chemoprevention strategy could reduce the incidence of mesothelioma.¹⁸⁷ As of yet, chemoprevention efforts in asbestos-exposed populations have not shown efficacy.¹⁸⁸

Screening of high-risk populations has the potential of detecting early lesions that could respond better to therapy. Screening trials of high-risk populations are ongoing to determine the value of routine low-dose CT scanning.¹⁸⁹ Serum mesothelin testing has a significant early pickup rate (15% to 40%), but it is not sensitive enough for use as a marker for early-stage mesothelioma; biomarkers with greater sensitivity are needed.¹⁹⁰

Additional information on clinical and basic research concerning mesothelioma can be found in reports of the biannual meetings of the IMIG.¹⁹¹ Independent websites include the National Cancer Institute (www.nci.nih.gov), Oncolink (Abramson Cancer Center, University of Pennsylvania; www.oncolink.com), and, for referral of patients for ongoing National Institutes of Health-sponsored studies, www.clinicaltrials.gov.

SOLITARY FIBROUS TUMOR OF THE PLEURA

Solitary fibrous tumors are mesenchymal tumors that can arise not only in the pleura but throughout the body.¹⁹² The term *solitary fibrous tumor* is now used in preference to earlier terms such as *benign mesothelioma* or *localized mesothelioma* for several reasons: to distinguish it clearly from malignant mesothelioma, to acknowledge that it may contain malignancy within it, and also to recognize that its cellular origin is more likely from pluripotent fibroblasts than from mesothelial cells.^{193,194} These localized tumors of the pleura are rarer than malignant mesotheliomas, accounting for 8% of all benign pathologic processes of the chest and 10% of all pleural neoplasms.¹⁹⁵ More than 50%

cause no symptoms and are identified as an incidental finding on radiographic examination.¹⁹⁶ When symptoms do arise, they are usually chronic and related to the mechanical effects of the tumor. Most commonly noted are cough, dyspnea, and chest pain.^{193,197}

Paraneoplastic syndromes are associated with this tumor. Hypertrophic osteoarthropathy has been described in 14%¹⁹⁷ to 19%¹⁹³ of patients and usually resolves over a few months following resection of the tumor.¹⁹³ Hypoglycemia has been described in between 4%¹⁹³ and 14%¹⁹⁷ of patients with solitary fibrous tumors, although the percentage may be overestimated because the hypoglycemia may be the factor that brings the patient to medical attention. The hypoglycemia arises from the production by the tumor of insulin-like growth factor 2, which has insulin activity peripherally and at the liver.¹⁹⁸ As in the case of other non-islet cell tumors associated with hypoglycemia, the hypoglycemia can be treated best by full resection of the tumor.¹⁹⁹ If this is not possible or if there is a delay while awaiting surgical resection, patients have been treated successfully with corticosteroids, which can suppress insulin-like growth factor 2 production.¹⁹⁹

Most solitary fibrous tumors arise from the visceral pleura, but some arise from the parietal.¹⁹⁷ In cases where they appear within the lung parenchyma, the tumor border may be attached to the pleura via a pedicle or stalk (see eFig. 56-11). They are usually round and firm with clear borders and can grow to be several centimeters in diameter. On cut section, the tumor has a fibrous whorled appearance with occasional calcification, hemorrhage, and central necrosis. Cells are elongated and spindle shaped on histologic examination. By immunohistochemistry, the solitary fibrous tumor can be distinguished from malignant mesothelioma by its staining for vimentin and CD34 (a hematopoietic progenitor cell antigen) and its lack of staining for keratin.^{197,200}

Imaging evaluation usually reveals a solitary circumscribed lesion (Fig. 82-6; see eFigs. 56-7, 56-8, 56-10, and 56-11). It rarely may occupy the entire hemothorax (see

Figure 82-6 Solitary fibrous tumor of the pleura. Axial CT image shows a large, somewhat heterogeneous mass in the right lower chest with extensive chest wall contact (arrows).

eFig. 56-9), but the average size is about 6 cm. In one study, most of the masses appeared to have an atypical appearance for pleural-based tumors in that they appeared to form an acute angle with the chest wall on radiographic examinations (eFig. 82-10).²⁰¹ This may be due to the size of the lesions and the tendency for them to hang from a pedicle into the lung.²⁰¹ In some cases, the mass may be mobile due to the pedicle, and occasionally movement can be documented using decubitus views. CT or MRI may reveal heterogeneous areas of enhancement in some larger tumors that correlate pathologically with areas of cystic necrosis and hemorrhage (see eFigs. 56-7 and 56-9). All have contours that are smooth or lobulated without evidence of invasion into underlying tissues. Occasionally dense calcification is seen.²⁰² MRI findings are consistent with a fibrous tumor with low signal on T1- and T2-weighted images (see eFigs 56-7C and D).²⁰³ There is little information about the use of PET to differentiate solitary fibrous tumors from malignant mesothelioma. However, the few cases in the literature support the finding of low or absent uptake of ¹⁸F-fluorodeoxyglucose on PET imaging of the solitary fibrous tumor (see eFig. 56-10C).²⁰⁴

The diagnosis is strongly suggested by the chest radiograph and CT scan. If a paraneoplastic syndrome is present together with a large tumor of the pleural space, the diagnosis of solitary fibrous tumor is likely. Needle biopsy may be unhelpful and, even if malignancy is present within a portion of the tumor, may miss the areas of concern. Surgery is advised in most cases both for diagnosis by excision and for definitive treatment.

Surgical resection will be curative in most cases. When the tumor arises from the visceral pleura, surgical resection may involve wedge resection or lobectomy. Recurrences have been documented many years after resection, sometimes with malignant transformation (see eFigs. 56-12 and 56-13).^{193,205} Annual chest radiographs are recommended to follow these patients after resection. Sometimes return of a paraneoplastic syndrome can accompany a recurrence of the solitary fibrous tumor.¹⁹⁷

Treatment of recurrent tumors can be difficult if re-resection is not possible. Current approaches targeting VEGF and angiogenesis pathways have shown promise.¹⁹²

PRIMARY EFFUSION LYMPHOMA

Primary effusion lymphoma (PEL) is a type of high-grade B-cell lymphoma that grows within the serous body cavities (pleural, peritoneal, and pericardial) without a detectable tumor mass (Fig. 82-7), although occasionally it may arise in extracavitary tissues.²⁰⁶ Because of its tropism for serosal spaces, it is considered one of the entities within the group of body cavity lymphomas.²⁰⁷ PEL is a body cavity lymphoma caused by the *human herpesvirus 8* (HHV8),²⁰⁷ the same virus that is the cause of Kaposi sarcoma. Most cases of PEL are found in homosexual men with advanced *human immunodeficiency virus* (HIV) disease. In a few cases, PEL has also been described in HIV-negative patients, usually elderly persons of Eastern European/Mediterranean descent, in an epidemiologic pattern similar to that of HIV-negative, classic Kaposi sarcoma.²⁰⁷ Many PELs in HIV-positive patients

Figure 82-7 Primary effusion lymphoma. On axial CT, the malignancy is manifest in bilateral effusions. Arrows indicate a minimally thickened parietal pleura, without nodularity.

display a coinfection with *Epstein-Barr virus* (EBV),²⁰⁷ suggesting a cooperative etiologic role between HHV8 and EBV. Nonetheless, the HHV8 is thought to be the primary etiologic factor, and the identification of HHV8 is required for the diagnosis of PEL.²⁰⁷

PEL tends to be a late manifestation of HIV infection. Therefore PEL should be considered in patients with advanced HIV disease with large exudative lymphocytic effusions. Chest CT scans will show a small degree of pleural thickening, without a tumor mass or mediastinal adenopathy²⁰⁸ (see Fig. 82-7). Pleural fluid may have a very elevated LDH level.¹⁹⁴ Cytologic examination will show pleomorphic large lymphocytes and suggest the diagnosis. The lymphocytes stain negatively for B- and T-cell antigens.²⁰⁹ Identification of HHV8 can be performed by extracting DNA from involved tissues followed by Southern blot analysis, by in situ hybridization of slides from paraffin-embedded samples, and by in situ reverse transcriptase polymerase chain reaction of cytologic smears or cell blocks.²¹⁰

Prognosis is poor, with survival reported between 6 months²⁰⁹ and 9 months²¹¹; prognosis may vary depending on the number of body cavities involved.²¹¹ Treatment is usually attempted with a CHOP-like regimen (cyclophosphamide, doxorubicin, vincristine, and prednisone) and, if the patient is HIV positive, with antiretroviral therapy.²¹² Some patients have shown benefit from antiretroviral therapy alone, suggesting that immune reconstitution can be effective against the lymphoma.²¹² As more is learned of the life cycle of HHV8, there is hope for specific therapy targeting the causative virus.²⁰⁹

PYOTHORAX-ASSOCIATED LYMPHOMA

Pyothorax-associated lymphoma (PAL) is an HHV8-negative lymphoma associated with EBV.²⁰⁷ It is a high-grade non-Hodgkin lymphoma arising as a mass in the pleural space of patients with long-standing chronic pleural inflamma-

tion usually following artificial pneumothorax for pleuropulmonary tuberculosis.²¹³ This entity is mainly seen in Japan but has also been reported in Western countries.^{213,214} The few series available report a strong association with EBV, with 70% of tumors having evidence of EBV in one study.²¹⁵ The cell type is usually B cell with frequent plasmacytoid features, but occasionally an aberrant dual B/T phenotype may be seen.²¹⁴ As opposed to PEL, which is associated with systemic immunodeficiency as from HIV or old age, PAL is associated with a local pleural immunosuppression and antigenic stimulation.²⁰⁷

A relatively large review of 106 patients with PAL in Japan showed the median age at the time of diagnosis to be 64 years (range, 46 to 82).²¹⁵ In these patients, there was at least a 20-year history of pyothorax (mean, 37 years, maximum, 64 years), and patients were predominately male (12:1). All had a history of chronic inflammation of the pleura, due to either artificial pneumothorax for treatment of pulmonary tuberculosis (80%) or tuberculous pleuritis (17%). Fever and/or back pain were the common symptoms on presentation, and chest radiograph or CT scan showed a localized pleural mass in an area of chronic pleural disease.²¹⁶ PET scans have been reported as showing intense uptake in the mass.²¹⁷ There are no large series evaluating specific treatments for this disease. In some reports, it appears that patients may do better with radiation therapy than with chemotherapy.^{218,219} In the review of 106 patient records, patients underwent a variety of treatments, including surgical resection, chemotherapy with CHOP-like regimen, or radiation therapy.²¹⁵ Patients appeared to respond initially to chemotherapy, but the clinical outcome was poor, with a 5-year survival of 22%.²¹⁵ In one patient undergoing treatment, the serum EBV load measured by a quantitative real-time polymerase chain reaction correlated well with tumor size, suggesting that monitoring of the serum EBV load might be helpful in the management of EBV-positive patients with this disease.²¹⁹

Key Points

- Malignant effusions are most commonly due to lung cancer, followed by breast cancer and lymphoma.
- Malignant effusions are often diagnosed by cytologic examination (60% of cases), with a high yield for adenocarcinoma and a low yield for squamous cell carcinoma. If cytologic results are negative, image-guided biopsy and thoracoscopy have a high yield (80% to 100%) for the diagnosis.
- Malignancy may involve the pleural space without formation of an effusion. In the seventh edition of tumor-node-metastasis staging for lung cancer, pleural malignancy with or without effusion is now classified as a metastatic lesion (M1a, intrathoracic metastasis).
- Palliation of malignant pleural effusions may include repeated taps, talc pleurodesis, or indwelling catheter drainage, with the choice depending on the life expectancy of the patient and whether the lung can reexpand. Indwelling catheter drainage can be an outpatient procedure and leads to symphysis and catheter removal in many patients.

- Pleural mesothelioma should be considered in any patient with a persistent undiagnosed exudate, especially if there is a history of exposure to asbestos, chest pain, a rindlike nodular thickening of the pleura, and involvement of the mediastinal pleura. Diagnosis may be suggested by an elevated mesothelin level in serum or pleural fluid but will require biopsy, often by thoracoscopy, for adequate tissue for panels of immunohistochemical stains.
- Pleural mesothelioma has been shown in a large prospective randomized trial to respond to cisplatin plus pemetrexed; although not studied in a randomized trial, surgery may play a role in debulking and as a part of multimodality therapy including chemotherapy and radiation therapy.
- Solitary fibrous tumors of the pleura are mesenchymal tumors that can involve the visceral pleura and are usually treated successfully with resection.
- *Primary effusion lymphoma* (PEL) and *pyothorax-associated lymphoma* (PAL) arise in the pleural space, the first presenting without a mass and the second as a mass. PEL is associated with systemic immunosuppression from HIV and is caused by human herpesvirus 8; PAL is associated with long-standing pleural inflammation and is associated with Epstein-Barr virus.

INTRODUCTION

The mediastinum is the region in the chest between the pleural cavities that contains the heart and other thoracic viscera, except the lungs. Interest in the mediastinum as a separate body region stems from the diversity and importance of the structures it contains and the multiplicity of disease processes by which it can be affected. The mass lesions that arise in the mediastinum represent a heterogeneous group of benign and malignant processes that defy easy categorization. The nonspecific clinical manifestations of most of these disorders and the relative inaccessibility for tissue sampling result in considerable challenges to the clinician evaluating mediastinal disease. This chapter

describes the normal anatomy and contents of the mediastinum, the clinical manifestations produced by mediastinal disease, and the means available for diagnostic investigation. It then describes the features of specific mediastinal tumors and cysts and outlines an overall clinical approach to the evaluation of mediastinal disease. The focus of the discussion of pathology is on lesions that arise primarily in the mediastinum; lung cancer is discussed as it pertains to findings in the mediastinum.

NORMAL ANATOMY OF THE MEDIASTINUM

The anatomy of the mediastinum is divided into anterior, middle, and posterior compartments.¹ This three-compartment model is consistent with embryonic development of the region and with the characteristic distribution of individual disorders encountered clinically. The anatomic relationships of the mediastinal viscera and tissue

Figure 83-1 Mediastinal compartments. **A**, By *anatomic* convention, the mediastinum is divided into anterior (A), middle (M), and posterior (P) compartments, as outlined on this lateral chest radiograph. **B**, Another method was developed to facilitate constructing an accurate differential diagnosis for mediastinal masses detected at chest radiography. Using this *radiologic* method, the anterior mediastinal compartment (A) is defined as the tissues residing anterior to a line drawn along the anterior aspect of the trachea and extended along the posterior cardiac margin, from the thoracic inlet to the diaphragm. The posterior mediastinal compartment (P) is defined as structures residing posterior to a line drawn 1 cm posterior to a line drawn along the anterior margins of the thoracic vertebrae; the middle mediastinal compartment (M) consists of those tissues residing between these two lines. (From Whitten CR, Khan S, Munneke GJ, Grubnic S: A diagnostic approach to mediastinal abnormalities. *Radiographics* 27:657–671, 2007.)

planes are best appreciated on axial images such as are shown schematically on a lateral chest radiograph in Fig. 83-1.²

The anterior compartment consists of everything anterior and superior to the heart; its boundaries are the sternum, the first rib, and an imaginary curved line following the anterior heart border and brachiocephalic vessels from the thoracic inlet to the diaphragm. Within the anterior compartment lie the thymus gland, any substernal extensions of the thyroid and parathyroid glands, and lymphatic tissue (Table 83-1).

The middle compartment, dorsal to the anterior mediastinum, extends from the lower edge of the anterior heart border along the diaphragm and then cranial along the posterior heart border and posterior wall of the trachea. It contains the heart, the pericardium, the aortic arch and its major branches, the innominate veins and *superior vena cava* (SVC), the pulmonary arteries and hila, the trachea, and several groups of lymph nodes. In addition, the phrenic and upper vagus nerves course through the middle mediastinal compartment.

The posterior compartment occupies the space between the back of the heart and trachea and the front of the posterior ribs and paravertebral gutters. It extends from the diaphragm cranial to the first rib. In it are the esophagus, descending aorta, azygos and hemiazygos veins,

ANTERIOR COMPARTMENT

Thymus gland
Substernal extensions of thyroid and parathyroid glands
Lymphatic vessels and lymph nodes
Connective tissue

MIDDLE COMPARTMENT

Heart
Pericardium
Aortic arch and great vessels
Innominate veins and superior vena cava
Pulmonary arteries
Trachea and main bronchi
Hila
Lymph nodes
Phrenic and upper vagus nerves
Connective tissue

POSTERIOR COMPARTMENT

Esophagus
Descending aorta
Azygos and hemiazygos veins
Paravertebral lymph nodes
Thoracic duct
Vagus nerves (lower portions)
Sympathetic chains
Connective tissue

paravertebral lymph nodes, and thoracic duct. The lower portions of the vagus nerve and sympathetic chains also lie within the posterior mediastinum.

CLINICAL PRESENTATIONS OF MEDIASTINAL DISEASE

MEDIASTINUM IN PATIENTS WITH MALIGNANCY

The most common reason that clinicians evaluate the mediastinum is in the staging of patients with lung cancer, because the extent to which the mediastinum is involved is crucial to management.³ Staging of lung cancer is discussed in greater detail in Chapters 21 and 53. Careful preoperative evaluation of the mediastinum is critical in determining a patient’s candidacy for surgical resection or other treatment modalities.^{4,5}

Nonthoracic malignancies also may metastasize to the mediastinum. This is particularly common in tumors originating in the head and neck, the esophagus, the genitourinary tract, the breasts, and the skin (malignant melanoma).

ASYMPTOMATIC MASS

The majority of mediastinal masses are discovered incidentally—at least half of all mediastinal masses are asymptomatic and detected by chest radiography performed for unrelated reasons. About 80% of such asymptomatic masses are benign, whereas more than half of those that produce symptoms are malignant.⁶⁻⁸

COMPRESSION OR INVASION OF ADJACENT TISSUES

Symptoms in patients with mediastinal mass lesions are usually caused by compression or invasion of adjacent intrathoracic structures.^{6,7} Chest pain, from traction on mediastinal tissues, tissue invasion, or bone erosion, is common. Cough may be due to extrinsic compression of the trachea or bronchi, erosion into the airway, and sometimes postobstructive pneumonia. Hemoptysis, hoarseness, or stridor also may be part of the clinical presentation. Invasion or inflammation of the pleural surface may produce a pleural effusion, and cause pain and dyspnea. Compression or direct invasion of the esophagus may lead to dysphagia. Rarely, anterior mediastinal tumors can cause pericarditis or pericardial tamponade, and masses in the middle mediastinum can produce right ventricular outflow obstruction and cor pulmonale.

The SVC is especially vulnerable to extrinsic compression and obstruction because it is thin-walled and has low intravascular pressure. The SVC syndrome results from increased venous pressure in the upper thorax, head, and neck⁹ and is characterized by dilation of collateral veins in the upper portion of the thorax and neck, edema and plethora of the face, neck, and upper torso, and suffusion and edema of the conjunctiva (see Fig. 53-5A and B). Neurologic symptoms such as headache, disturbance of consciousness, and visual distortion, may be present. Symptoms are exacerbated

in the supine position. Numerous benign causes of SVC syndrome are described,¹⁰ but bronchogenic carcinoma (Video 83-1 and eFig. 83-1) and lymphoma (Video 83-2 and eFig. 83-2) are now the most common etiologies.^{11,12}

The compression or invasion of nerves may result in hoarseness from involvement of the recurrent laryngeal nerve, Horner syndrome from involvement of sympathetic ganglia, dyspnea from involvement of the phrenic nerve causing diaphragmatic paralysis, tachycardia from involvement of the vagus nerve and clinical manifestations of spinal cord compression.

SYSTEMIC SYMPTOMS AND SYNDROMES

Fever, anorexia, weight loss, and other systemic symptoms are nonspecific features of malignancy and inflammation that may manifest in patients with mediastinal disease.

In addition, primary mediastinal tumors are associated with a wide array of distinctive systemic syndromes (Table 83-2).^{6,7,13-15} Some typically have endocrine activity, such as intrathoracic goiter, which may present with thyrotoxicosis. Cushing syndrome is associated with thymomas and carcinoid tumors. Thymomas are classically associated with myasthenia gravis (Video 83-3 and eFig. 83-4), in addition to other systemic syndromes. Patients with human chorionic gonadotropin-secreting germ cell tumors may manifest with gynecomastia; patients with pheochromocytoma may present with hypertension. Hypercalcemia may be a presenting abnormality observed in patients with parathyroid adenoma and lymphoma. Hypoglycemia in patients with certain pleural tumors, teratomas, fibrosarcomas, and neurosarcomas is also believed to be the result of tumor products with endocrine activity.

Table 83-2 Systemic Syndromes Associated with Mediastinal Masses

Syndrome	Associated Conditions
ENDOCRINE EFFECTS	
Hypothyroidism or hyperthyroidism	Mediastinal goiter
Hypercalcemia	Parathyroid adenoma, lymphoma
Hypertension	Pheochromocytoma, ganglioneuroma, chemodectoma
Cushing syndrome	Carcinoid, thymoma
Hypoglycemia	Mesenchymal tumor
Gynecomastia	Germ cell tumor
Diarrhea	Ganglioneuroma, neuroblastoma
AUTOIMMUNE EFFECTS	
Opsomyoclonus	Neuroblastoma
Myasthenia gravis	Thymoma
Red cell aplasia	Thymoma
Myocarditis	Thymoma
Hypogammaglobulinemia	Thymoma
CONGENITAL SYNDROMES	
Neurofibromatosis	Neurofibroma
Multiple endocrine neoplasia	Parathyroid adenoma, pheochromocytoma
UNKNOWN CAUSES	
Alcohol-induced pain	Hodgkin lymphoma
Fever and night sweats	Lymphoma

IMAGING THE MEDIASTINUM

The mediastinum is relatively inaccessible for examination or exploration. Accordingly, imaging studies play an important role in the initial evaluation of mediastinal disease. These include conventional radiographic studies, *computed tomography* (CT), *magnetic resonance imaging* (MRI), trans-thoracic and endoscopic ultrasonography, PET, and other radionuclide studies.

CONVENTIONAL RADIOGRAPHIC TECHNIQUES

Most mediastinal abnormalities are first detected by standard posteroanterior and lateral chest radiographs, and certain mediastinal mass lesions have characteristic findings (Table 83-3). For example, teratomas are usually ante-

rior and may contain areas of calcium (sometimes teeth or bone), fat, and soft tissue. Neural tumors lie posteriorly and have sharply delineated margins. Bronchogenic cysts tend to lie against the trachea, carina, or main bronchus. These findings give clues to the possible origin of a mediastinal mass, but further imaging evaluation is usually required.

In the appropriate clinical settings, contrast studies remain important diagnostic tools in mediastinal disease. Barium esophagrams can demonstrate extrinsic compression, esophageal diverticulum, tumor invasion, or fistula formation.⁶ Angiography can identify vascular compression or invasion, can define the vascular supply of tumors, and can sample blood for hormonal localization of certain tumors. Myelography may help delineate intraspinal extension of posterior mediastinal tumors and differentiate neurogenic neoplasms from meningoceles. For the most part, these techniques have been supplanted by CT and MRI.

COMPUTED TOMOGRAPHY

CT imaging is the mainstay of radiographic evaluation of the mediastinum, because this modality can firmly determine the anatomic location, morphology, and tissue density of a mass. The transaxial plane of CT is well suited for assessment of mediastinal structures, most of which are oriented perpendicularly to this plane. Administration of intravenous contrast helps delineate vascular structures as they relate to a mass and other mediastinal structures. Easily identified CT patterns include the high density of calcified tissue and contrast-enhanced blood vessels, and the characteristic low density of fat (Fig. 83-2).¹⁶ Normal anatomic variations and fluid-filled cysts can be distinguished confidently from bulky solid masses, which may be irregularly bordered and possess necrotic areas. Additionally, the site of origin of mediastinal masses can be better identified.¹⁷ Characteristic CT findings in a variety of mediastinal disorders have been described (see Table 83-3). For example, the specificity of the CT appearance of teratomas (Video 83-4, eFigs. 83-9 and 83-10), thymolipomas (Video 83-5 and eFig. 83-11), and omental fat herniation (Video 83-6 and eFig. 83-12) is 100%, but the overall accuracy of CT for predicting the diagnosis of all mediastinal masses is less than 50%.¹⁶

Lymph nodes are readily identifiable on CT scan and can be categorized by size and morphology. Mediastinal lymph nodes greater than 1 cm in diameter in the short axis are considered to be abnormally enlarged and are suspicious for malignancy in the proper clinical context. Mediastinal lymph nodes greater than 2 cm in diameter are virtually always abnormal. In the most recent systematic review of studies on the use of CT in mediastinal staging of lung cancer, the median sensitivity and specificity for identifying metastatic lymph nodes using the greater than 1 cm criteria were 55% and 81%, respectively,¹⁸ similar to what was previously reported by Gould and coworkers.¹⁹ However, even in series of patients with proven bronchogenic carcinoma, benign findings were present in 10% to 37% of lymph nodes that were either larger than 2 cm in diameter or had evidence of central necrosis.^{20,21}

Even though CT cannot reliably distinguish between benign and malignant disease, it remains the initial imaging procedure of choice for the evaluation of the mediastinum

Table 83-3 Characteristic Radiographic Findings in Mediastinal Disease

Feature	Likely Etiology
Bulky mass on initial presentation	Anterior: lymphoma, germ cell tumor, thymoma or thymic carcinoma Posterior: neurogenic tumor
Teardrop-shaped mass within interlobar fissure	Pericardial or bronchogenic cyst
Fat density on CT scan	Mediastinal lipomatosis or lipoma
Calcification in mass	In rim of mass: Cystic thymoma or thyroid adenoma Aneurysm Silicosis ("eggshell" calcification) In center of mass: Thyroid adenoma Teratoma
Teeth or bone	Teratoma
Phleboliths	Hemangioma
Air-fluid level in mass	Esophageal disease Diaphragmatic hernia Developmental cyst Cystic teratoma Abscess
Mass with associated parenchymal opacity	Granulomatous inflammation/infection Metastatic bronchogenic carcinoma Lymphoma with direct extension into lung Esophageal abnormality with aspiration pneumonitis Bronchial compression by primary mediastinal mass
Mass with associated pleural effusion	Metastatic malignancy with pleural involvement Granulomatous inflammation of lymph nodes
Superior vena cava obstruction	Recent onset: Bronchogenic carcinoma Lymphoma Catheter-associated thrombosis Long-standing: Mediastinal fibrosis
Erosion or destruction of bone	Arterial aneurysm Tumors of peripheral nerves or sympathetic ganglia Meningocele
Spine or rib deformity	Enteric cyst

Figure 83-2 Mediastinal lipomatosis. Chest radiograph (A) showing diffuse mediastinal widening (arrows) and chest CT scan (B) showing extensive fat deposition (arrows) in the anterior mediastinum in a patient with mediastinal lipomatosis.

in patients with a primary mediastinal mass¹³⁻¹⁵ or with suspected lung cancer.²² CT can precisely define the mediastinal anatomy and guide subsequent invasive diagnostic and staging procedures, or can confirm a clinical suspicion of extensive mediastinal involvement or visceral organ invasion that precludes curative resection.

MAGNETIC RESONANCE IMAGING

Although much less frequently used than CT in evaluating mediastinal lesions, MRI offers several potential advantages over CT. MRI assesses tissues by measuring radiofrequency-induced nuclear resonance emissions, and the better contrast resolution over CT is advantageous in evaluating soft tissue structures and tissue boundaries (Fig. 83-3).²³⁻²⁶ Blood vessels are identifiable without the need for contrast enhancement (Fig. 83-4) (Videos 83-7A and B), thus MRI can provide an alternative to patients who cannot be given iodinated contrast material required by CT. Ionizing radiation exposure is also eliminated.²⁷

MRI has utility in evaluating neurogenic tumors, and it may also be useful in evaluating thymoma and distinguishing it from congenital cyst or thymic carcinoma.²⁸ MRI can be helpful for defining anatomy before surgical resection of superior sulcus tumors or those invading the mediastinum, chest wall, or diaphragm.^{4,22}

Whereas CT is more commonly used for routine staging of lung cancer, MRI may be useful for defining anatomy in special circumstances, such as before surgical resection of superior sulcus tumors or tumors invading the mediastinum, chest wall, or diaphragm.^{5,23} A large multicenter study comparing CT and MRI in patients with lung cancer found similar accuracy for the detection of mediastinal node involvement, but MRI was superior for detecting direct mediastinal tumor invasion (Video 83-8 and eFig. 83-15; see also Chapter 18).²⁹ Diffusion-weighted MRI distinguished between malignant and benign mediastinal lesions based on apparent diffusion coefficient levels with a sensitivity of 95% and specificity of 87% in a study of 53 mediastinal lesions,²⁴ with evidence of lower apparent diffusion coefficient values indicating a slower diffusion of water molecules in the malignant lesions. However, the use

Figure 83-3 Magnetic resonance lymphogram of the thoracic duct. The normal course of the thoracic duct can be seen crossing diagonally through the lower mediastinum from the patient's right to left and then ascending along the left mediastinum to reach the subclavian vein. In this case the duct is somewhat more dilated and tortuous than normal due to the presence of hepatic cirrhosis. (From Takahashi H, Kuboyama S, Abe H, et al: Clinical feasibility of noncontrast-enhanced magnetic resonance lymphography of the thoracic duct. *Chest* 124:2136–2142, 2003.)

of MRI to establish malignancy or benignity requires further study.

ULTRASONOGRAPHY

Ultrasonography can confirm the cystic nature of mediastinal masses, but it cannot readily distinguish between benign and malignant cystic lesions. Both transthoracic and endoscopic ultrasound probes are useful in the evaluation of mediastinal disease in the context of guiding endoscopic biopsy procedures.³⁰

Figure 83-4 Magnetic resonance imaging of superior vena cava syndrome. A 52-year-old woman with multiple myeloma experienced symptoms of superior vena cava (SVC) obstruction following placement of an indwelling central venous catheter in preparation for bone marrow transplantation. Vertically oriented structures are clearly discernible, and black “flow void” is present within the heart and great vessels. The SVC is completely obstructed by thrombus (arrow).

NUCLEAR IMAGING

Nuclear imaging studies rely on the localization of markers based on specific metabolic or immunologic properties of the target tissue to provide a functional image of a lesion. The spatial resolution of radionuclide scans is relatively poor, but the overall diagnostic accuracy may be high if a sufficiently specific probe is available. Nuclear studies offer the potential to identify a primary malignancy and identify distant metastases with a single scan of the entire body.

PET is a widely used nuclear imaging technique that relies on high-energy photon-emitting probes, such as ^{18}F -fluorodeoxyglucose (FDG), which are chemically trapped within metabolically active neoplastic cells. The result is a high signal-to-background ratio and excellent spatial resolution for a functional image of a tumor (Fig. 83-5). More recently, use of combined and co-registered PET and CT images has allowed for more accurate anatomic localization of the lesions in question but at the cost of lower specificity and increased false-positive results.^{18,31}

The use of PET in the evaluation of the mediastinum is largely focused on metastatic disease from thoracic malignancies, because it is useful in staging and preoperative planning for lung cancer. In the evaluation of suspected lung cancer, PET can identify metastatic foci in the mediastinum and extrathoracic sites and help determine the optimal biopsy approach that will make a histologic diagnosis as well as stage the disease.³² Despite widespread use of PET scanning, standardized quantitative criteria for defining an abnormal scan are lacking, and accuracy is far from perfect.³³ False-positive results can be caused by granulomatous, inflammatory, or infectious conditions. FDG-PET

Figure 83-5 Chest CT and PET scans of a patient with right upper lobe squamous cell carcinoma. The primary tumor and right paratracheal adenopathy (A) and subcarinal adenopathy (B) are evident on the standard CT images (arrows). PET images reveal probe uptake in the primary tumor and right paratracheal nodes on axial (C) (arrow) and coronal (D) views, but not in the subcarinal node on coronal (D) (arrow) and axial (E) views. The arrowheads in E point to the main bronchi. At mediastinoscopy, the right paratracheal nodes were found to be malignant, and the subcarinal nodes were enlarged but benign. (From Vansteenkiste JF, Stroobants SG, De Leyn PR, et al: Mediastinal lymph node staging with FDG-PET scan in patients with potentially operable non-small cell lung cancer: a prospective analysis of 50 cases. *Leuven Lung Cancer Group. Chest* 112:1480–1486, 1997.)

Figure 83-6 Mediastinal lymphoma. **A**, Chest radiograph of a 36-year-old man with gray zone lymphoma presenting as a bulky mediastinal mass. **B**, PET-CT scan performed before initiation of treatment shows a hypermetabolic anterior mediastinal mass with invasion of the chest wall and pectoralis muscles as well as involvement of axillary lymph nodes.

has been shown to be more accurate than CT for mediastinal staging of lung cancer with a sensitivity of 80% and a specificity of 88% in an updated meta-analysis¹⁸; when lymph nodes are enlarged by CT criteria, sensitivity increases while specificity decreases.¹⁹ Mediastinal lymph node sampling is warranted in the setting of a positive PET scan if the findings of mediastinal involvement would alter the subsequent surgical approach (see Chapters 21 and 53).

The utility of PET for the evaluation of primary mediastinal lesions is not as well established as it is for metastatic disease. FDG-PET may differentiate between thymoma and thymic carcinoma,³⁴ but has low sensitivity in differentiating between nonaggressive and aggressive subtypes of thymoma.²⁸ It is not used routinely for staging of thymoma. However, PET is considered standard of care in the pretreatment workup and follow-up of mediastinal lymphoma (Fig. 83-6). FDG-PET also plays a role in detecting residual post-chemotherapy malignant germ cell tumors, specifically seminomas, of the mediastinum. There is little role for PET in evaluating neurogenic tumors.³⁵ Hypermetabolic lesions in the mediastinum may also represent sarcoidosis, mycobacterial and fungal infection, or brown fat.

Other nuclear medicine techniques for the evaluation of the mediastinum include radioiodine scanning for the detection of ectopic thyroid tissue; a positive result is pathognomonic for that condition.⁶ This approach must be planned carefully because iodinated contrast administered intravenously for a CT scan may prevent the uptake of radioiodine for several weeks or more.

TECHNIQUES FOR OBTAINING MEDIASTINAL TISSUE

Definitive diagnosis of most mediastinal masses requires the evaluation of a tissue sample. However, biopsy of mediastinal tissue should be reserved for instances when diagnostic results will influence subsequent treatment. The decision to perform a biopsy rather than surgical resection is based on the presumptive diagnosis. If definitive surgical resection is the treatment choice regardless of the results of a biopsy, then a “diagnostic delay” should be avoided.

Available approaches for biopsy of mediastinal lesions include needle aspiration and biopsy via transbronchial,

percutaneous, or transesophageal approaches. Surgical biopsies are obtained by more invasive procedures including mediastinoscopy and thoracoscopy.

IMAGE-GUIDED BIOPSY

Endobronchial Ultrasound-Guided Transbronchial Needle Aspiration

For evaluation of mediastinal adenopathy or other lesions in the middle mediastinum, *transbronchial needle aspiration* (TBNA) via the fiberoptic bronchoscope offers a less invasive option to surgical mediastinoscopy. Although few significant complications have been reported, the sensitivity of blind TBNA is low, ranging from 14% to 50%.³⁶⁻³⁸

Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) is a recent technology that has significantly improved the ability of pulmonologists to diagnose and stage non-small cell lung cancer in a minimally invasive manner. With the advent of a curvilinear ultrasound probe integrated at the end of the bronchoscope, TBNA with a 22-gauge needle can be performed under real-time ultrasonographic guidance. The ability to visualize the area of interest as well as adjacent vascular structures has vastly improved diagnostic yields.³⁹⁻⁴¹ Upper and lower paratracheal, subcarinal, and hilar lymph nodes are readily accessible by EBUS-TBNA, as is any mediastinal or hilar lesion that is adjacent to the large airways. EBUS-TBNA has the advantage over mediastinoscopy in accessing the posterior subcarinal lymph nodes as well as hilar nodes or masses, in addition to being an ambulatory procedure with lower associated health care costs.⁴²

While the efficacy of EBUS-TBNA is now firmly established in the evaluation of lung cancer, there is also an increasing role for the initial evaluation of isolated mediastinal adenopathy due to other conditions such as sarcoidosis. In a randomized controlled trial of 50 patients with clinically suspected sarcoidosis due to the presence of mediastinal and hilar adenopathy, the diagnostic yield of EBUS-TBNA was superior to blind TBNA, with a sensitivity of 83% and specificity of 100%.⁴³ In a prospective trial of 77 patients with isolated mediastinal adenopathy, a specific diagnosis of sarcoidosis, tuberculosis, lymphoma, or other malignancy was made in 67 of them, thus obviating the need for a more invasive surgical mediastinoscopy.⁴⁴

EBUS-TBNA can be useful in providing a definitive diagnosis of primary or recurrent lymphoma; however, its role in the initial diagnosis of mediastinal lymphoproliferative disorders is controversial because the amount of tissue provided may not be adequate for histologic subtyping.^{44,45}

Endoscopic Ultrasound-Guided Needle Aspiration and Biopsy

Endoscopic ultrasound (EUS)–guided sampling relies on the placement of biopsy needles that are passed through the working channel of a gastroscope.⁴⁶ The proximity of the esophagus to mediastinal sites relatively inaccessible to mediastinoscopy, such as the posterior subcarinal lymph nodes, makes this approach particularly useful in selected cases. EUS-guided biopsy has similar sensitivity as PET for determining inoperability in lung cancer and, importantly, superior specificity (100% vs. 72%).⁴⁷ In selected cases, it can confirm the presence of mediastinal metastases and thereby obviate the need for surgical staging procedures.⁴⁸

Percutaneous Needle Aspiration and Biopsy

Percutaneous needle aspiration and biopsy of mediastinal masses, usually in the anterior compartment, can be performed using ultrasound or, more often, CT guidance⁴⁹ (Fig. 83-7). Percutaneous needle aspiration of the mediastinum has acceptable morbidity and yields comparable to those from percutaneous biopsy of pulmonary lesions. As with TBNA, serious bleeding is seldom encountered,⁴⁹ and accurate diagnosis of a wide variety of lesions has been reported.

SURGICAL BIOPSY

Mediastinoscopy

Mediastinoscopy allows direct inspection and biopsy of lymph nodes or other masses in the superior portion of the anterior mediastinum.⁵⁰ Cervical mediastinoscopy provides access to the paratracheal and subcarinal lymph nodes, whereas an anterior mediastinotomy (otherwise known as

an anterior or parasternal mediastinoscopy) provides access to the lymph nodes in the aortopulmonary window. Although more invasive than a percutaneous or endobronchial approach, mediastinoscopy has the advantage of providing the entire lymph node for histologic examination, rather than the cellular aspirates or small tissue fragments produced by needle biopsy techniques. Mediastinoscopy is most frequently used in the staging of bronchogenic carcinoma,⁵¹ but has utility in evaluating mediastinal adenopathy or mass lesions of other etiologies. Either frozen section or imprint cytology methods can provide rapid, accurate results and facilitate immediate decisions about the feasibility of curative resection.^{52,53}

Mediastinal anatomy from the perspective of the surgeon performing a mediastinoscopy is different from that based on the lateral chest radiograph as described earlier. For mediastinoscopy, structures are considered according to whether they lie anterior, posterior, or immediately to the right or left of the trachea.² Mediastinoscopy is performed using general anesthesia, but is typically an outpatient procedure when subsequent thoracotomy is not planned to follow immediately.⁵⁴

Mediastinoscopy is safe and well tolerated. Complications of mediastinoscopy include pneumothorax, hemorrhage, recurrent laryngeal nerve or phrenic nerve paralysis, injury to the trachea, esophageal perforation, thoracic duct laceration, air embolism, and mediastinitis.

Video-Assisted Thoracoscopic Surgery

Biopsies of mediastinal lymph nodes can also be performed by *video-assisted thoracoscopic surgery* (VATS). VATS provides access to the hilar nodes and inferior pulmonary ligament lymph nodes on both sides. Additionally, on the right side, VATS can provide access to the right paratracheal lymph nodes and subcarinal nodes. Left-sided VATS can provide access to the aortopulmonary nodes. VATS can also be a tool for the evaluation of pleural and lung abnormalities in the management of mediastinal diseases. After dissection through the mediastinal pleura, mediastinal lymph nodes can be sampled to aid in the staging of malignancies such as esophageal carcinoma and for the diagnosis and resection of primary mediastinal tumors and cysts.⁵⁵⁻⁵⁸ VATS requires a general anesthetic, chest tube placement at the conclusion of the procedure, and typically a limited stay in the hospital.

Figure 83-7 CT-guided needle aspiration of an anterior mediastinal mass. The image shows the needle entering the mass by passing lateral to the sternum and medial to the internal mammary vessels (arrow, left internal mammary artery). Associated findings include a pretracheal lymph node and bilateral pleural effusions.

MEDIASTINAL MASS

CLASSIFICATION

Mediastinal masses are considered primary, that is, arising solely from structures within the mediastinum, or secondary, usually as metastatic disease from intrathoracic or extrathoracic malignancy.

The most practical clinical classification of primary mediastinal masses groups together lesions that are characteristically found in the anterior, middle, or posterior mediastinal compartments (Table 83-4), with the recognition that such a simplified scheme overlooks the fact that mediastinal masses will not necessarily respect anatomic borders. Masses found within any of the mediastinal compartments

Table 83-4 Disorders Presenting as a Mass in the Mediastinum

Anterior Mediastinum	Middle Mediastinum	Posterior Mediastinum
Thymic neoplasms	Lymphadenopathy	Neurogenic tumors
Germ cell tumors	Reactive and granulomatous inflammation	Meningocele
Teratoma	Metastasis	Esophageal lesions
Seminoma	Angiofollicular lymphoid hyperplasia (Castleman disease)	Carcinoma
Nonseminomatous germ cell tumors	Lymphoma	Diverticula
Embryonal cell carcinoma	Developmental cysts	Diaphragmatic hernia (Bochdalek)
Choriocarcinoma	Pericardial cyst	Miscellaneous
Lymphoma	Foregut duplication cysts	
Hodgkin lymphoma	Bronchogenic cyst	
Non-Hodgkin lymphoma	Enteric cyst	
Thyroid neoplasms	Others

may be due to lesions more commonly found in another mediastinal compartment or due to those that have extended from another area in the mediastinum (Fig. 83-8).

In a series of 400 consecutive patients with a primary mediastinal lesion,⁵⁹ 25% had a primary cystic lesion and 42% had a malignant lesion. The anterior compartment was the most common compartment for a lesion, which was more likely to be malignant, followed by the posterior and then middle compartments. Although two thirds of mediastinal masses are benign, the likelihood of malignancy depends on the location, age of the patient, and presence or absence of symptoms.^{60,61} In a series of 38 patients with malignant mediastinal tumors, 31 had at least one sign or symptom.⁶¹

INCIDENCE

The true incidence of primary mediastinal masses is difficult to ascertain. In a study of more than 9000 patients in a lung cancer CT screening trial, the prevalence of an incidentally detected mediastinal mass was 0.77%; on follow-up annual screening, the incidence was 0.01%.⁶² Historically, thymomas and developmental cysts were the most common masses found in adults, followed by neurogenic tumors and lymphoma, based on the collection by Silverman and Sabiston of nearly 2400 cases from the literature (Table 83-5).⁶ More recent series suggest a similar pattern,^{8,63} although Cohen and associates⁸ have observed both a rising incidence of mediastinal masses in general and an increasing proportion of lymphoma and malignant neurogenic tumors over the course of their 45-year survey. Neurogenic tumors, thymomas, and developmental cysts account for about 60% of all mediastinal masses. Lymphomas and germ cell tumors such as teratoma and seminoma account for about 25%, and a large number of other lesions, both benign and malignant, constitute the remaining 15%.⁸

SPECIFIC MEDIASTINAL TUMORS AND CYSTS

LESIONS OF THE ANTERIOR MEDIASTINUM

Thymic Neoplasms

Thymoma is the most common neoplasm arising in the anterior mediastinum^{6,7,17,64} and is increasingly recognized in the course of thorough evaluations of patients with myasthenia gravis.⁶ It remains a rare tumor, with an overall incidence of 0.13 per 100,000 person-years in the United States.⁶⁵ The peak incidence of thymomas is between the ages of 40 and 60 years and is higher in Asians and African Americans, with equal gender predilection.

Although most thymomas are not biologically aggressive, about one third of thymomas found have already invaded their capsules. Advanced disease involves extension into local structures and transdiaphragmatic extension into the abdomen and pericardial involvement, but lymphogenous and hematogenous metastases are rare.⁶¹ The histologic classification remains a subject of debate and revision.²⁸ The current World Health Organization classification system, which is based on histologic features, does not accurately predict clinical outcome, thus treatment of patients has been based historically on the presence and degree of tumor invasion into microscopic and local structures. Most clinicians use the Masaoka clinical staging system, which is based on the degree of invasion of the tumor through the capsule into adjacent structures.⁶¹ Moran and colleagues recently proposed a new staging system in which the overall prognosis and recurrence is based on extent of tumor infiltration.⁶⁶ Currently the *International Thymic Malignancies Interest Group* (ITMIG) and the *International Association for the Study of Lung Cancer* (IASLC) are collaborating on developing a new TNM-based classification system, which is expected in 2017.^{66a}

Figure 83-8 Thymoma. Typical findings on chest radiograph (A, frontal view) and chest CT (B) showing a mass presenting in the anterior and middle mediastinum. At surgery, this mass proved to be a benign thymoma, originating in the anterior mediastinum and extending by a slender stalk into the middle compartment. (Courtesy Dr. Robert Stevens, Wenatchee, WA.)

Clinically, the majority of patients with thymoma are asymptomatic, while one-third of patients will present with nonspecific chest pain, cough, or dyspnea due to local tumor effects.⁶⁷ Forty to 70% have at least laboratory evidence of one or more of the two dozen systemic “parathymic” syndromes that have been recognized.⁶ Thymomas are associated with numerous systemic syndromes, most of which appear to be autoimmune in origin.^{6,7,14} The most familiar of these is myasthenia gravis, reported in 10% to 50% of patients with thymoma⁶ and thought to be due to autoantibodies to the postsynaptic acetylcholine receptor.^{68,69} Other associated syndromes include pure red blood cell aplasia, myocarditis, and hypogammaglobulinemia. Patients with thymoma also have an increased incidence of collagen vascular disease, Whipple disease, and malignancy elsewhere in the body.

On chest radiography, thymomas appear as an ovoid, smooth or lobulated unilateral mass near the junction of the heart and great vessels (Fig. 83-9).⁷⁰ Compared with thymic hyperplasia, which is typically symmetrical,

*Based on Silverman and Sabiston's review of reported mediastinal masses in 1950 adults and 437 children.

Data from Silverman NA, Sabiston DC Jr: Mediastinal masses. *Surg Clin North Am* 60:757-777, 1980.

thymoma usually distorts the gland's normal shape and extends to one side.⁷¹ On CT scan, most thymomas present as a solid 5- to 10-cm anterior mediastinal mass outlined by fat; up to one third of thymomas contain cystic, necrotic, or hemorrhagic areas that enhance heterogeneously. Contrast CT is necessary for the staging of thymoma, specifically for discerning vascular involvement. MRI can help distinguish benign cysts from a cystic thymoma or thymic carcinoma. At this time, nuclear medicine has little role in the evaluation of thymoma. Due to their relatively indolent nature, most thymomas have low FDG uptake, which limits the utility of PET imaging to discern a benign from a malignant thymic mass.^{28,61}

The mainstay of therapy for thymomas is surgical resection, which provides the best chance for an optimal prognosis.⁶¹ Adjunctive treatment with postoperative radiotherapy is typically provided,^{7,64,72} and the addition of preoperative or adjuvant chemotherapy appears promising for more advanced stages.⁷³⁻⁷⁵

Patients whose tumors are fully encapsulated with no evidence of invasion can expect postoperative survival equal to that of the general population. Invasive tumors have a poorer prognosis, with 50% to 77% 5-year and 30% to 55% 10-year survival.⁷⁶ Thymoma recurs after resection in nearly a third of patients.⁷⁶ The largest and most recent retrospective survey of thymic tumors from the European Society of Thoracic Surgeons database showed that higher Masaoka stage (with evidence of invasion), incomplete resection, and nonthymoma histology were factors in recurrence and worsening survival.^{76a}

Thymic carcinoma is an aggressive epithelial malignancy that invades locally and frequently metastasizes.^{77,78} This rare cancer develops predominantly in middle-aged men, who present with symptoms of cough, dyspnea, and chest pain as well as nonspecific systemic symptoms.⁶¹ On imaging, thymic carcinomas are heterogeneous masses with areas of necrosis and calcifications. They are highly FDG-avid on PET scan.^{28,34} The prognosis, which depends

Figure 83-9 Thymoma. **A**, Frontal chest radiograph shows a smoothly margined mass along the right side of the mediastinum (arrows). **B**, Axial magnetic resonance T1-weighted image through the base of the heart shows that the mass (arrows) is slightly hyperintense compared to the skeletal muscle and resides within the anterior mediastinum. Note the smooth, well-defined margins of the mass, consistent with an encapsulated thymoma.

on the histologic grade and the anatomic stage, is generally poor. Surgical resection is the treatment of choice; chemotherapy and radiation therapy are advocated for unresectable disease.

Carcinoid tumors occasionally arise in the thymus.^{79,80} They may cause Cushing syndrome and be associated with multiple endocrine adenomatosis. Locally invasive carcinoids may be difficult to resect completely, but characteristically have a prolonged clinical course.⁶ Interestingly, the thymus is also a common site for mediastinal Hodgkin lymphoma, and normal thymic tissue may enlarge following chemotherapy for lymphoma (a process termed *thymic rebound*) (eFig. 83-25), mimicking recurrence of the primary disease.⁸¹ Other thymic mass lesions include benign conditions such as thymic hyperplasia (eFig. 83-26), thymic cysts, and lipothymomas (see Video 83-5 and eFig. 83-11).⁸²

Germ Cell Tumors

Approximately 10% to 12% of primary mediastinal masses are derived from multipotent germ cells that migrated abnormally during early embryonic development.^{6,7,83,84} These neoplasms are classified into three groups: benign teratoma, seminoma, and nonseminomatous germ cell tumors.⁸⁴

Teratomas, the most common germ cell tumors, are by definition made up of tissues foreign to the area in which they arise. Ectodermal derivatives predominate, but structures originating in all three primary germ cell layers may be found. *Dermoid cyst* refers to a lesion that contains only the epidermis and its derivatives. Teratomas arise most often in young adults, but have been reported in all age groups; men and women are affected with equal frequency. Most patients with teratomas have symptoms caused by the tumor; only about a third are asymptomatic.^{6,85} Usual symptoms are pain, cough, and dyspnea. Teratomas can rupture into the pleural space or into the pericardium. If the tumor erodes into a bronchus, the patient may have hemoptysis or even expectorate differentiated tissue such as hair (trichoptysis) or sebaceous material.⁸⁵

On chest radiographs, teratomas appear smooth, rounded, and circumscribed if they are cystic. Solid lesions can appear lobulated and asymmetric. On CT scans (see Video 83-4 and eFig. 83-10), soft tissue, fat, and calcifica-

Figure 83-10 Teratoma. Axial CT image through the base of the heart shows a large right-sided anterior mediastinal mass with heterogeneous attenuation. Elements of calcium, soft tissue, and fat (*) are present. The presence of fat within an anterior mediastinal mass is most consistent with teratoma.

tion (occasionally, fully formed teeth and bone) can be identified, rendering this one of few mediastinal tumors that can be diagnosed confidently before operation¹⁶ (Fig. 83-10). All teratomas should be resected due to malignant potential and effects of impingement on adjacent vital structures. In malignant teratoma, adjuvant combination chemotherapy may result in improved survival.⁸⁶

Seminomas and nonseminomatous germ cell tumors are malignant and nearly always cause symptoms. These lesions appear as a large anterior mediastinal mass on chest imaging (Video 83-9 and eFig. 83-29). Seminomas are seen almost exclusively in men, usually in the third decade of life.⁷ Most patients seek medical attention because of chest pain, dyspnea, cough, hoarseness, or dysphagia. Seminomas are aggressive malignant tumors that extend locally and metastasize distantly, usually to skeletal structures. The tumor can obstruct the SVC. They may secrete human chorionic gonadotropin, but not alpha-fetoprotein. Factors associated with a poor prognosis include age older than 35 years, SVC obstruction, supraclavicular, cervical, or hilar

adenopathy, and fever.^{87,88} Seminomas are extremely radiosensitive and may respond dramatically to chemotherapy, even in cases with dissemination.^{84,89} With aggressive cisplatin-based regimens, long-term survival for all mediastinal seminomas is approximately 80%.^{84,90}

Nonseminomatous mediastinal germ cell tumors include embryonal cell carcinoma and choriocarcinoma.^{6,7,87} Like seminoma, these tumors develop mainly in men in the third and fourth decades and are usually symptomatic. These malignancies carry a poorer prognosis relative to cancers arising from the gonads.⁸⁴ Embryonal cell carcinoma is also called endodermal sinus or yolk sac tumor (Video 83-10 and eFig. 83-30). These highly aggressive tumors often secrete human chorionic gonadotropin, alpha-fetoprotein, or carcinoembryonic antigen. Human chorionic gonadotropin may also produce clinical manifestations, such as gynecomastia, in 50% of patients.⁷ Associations have been noted with Klinefelter syndrome⁹¹ and with hematologic malignancy.⁹² Most patients present with disseminated disease, and the prognosis has been less favorable than in seminoma.⁷ Cisplatin-based treatment regimens have markedly improved the outcome, with more than 50% of patients achieving long-term survival.^{84,92} Long-term survival may also be possible in those who undergo a complete surgical resection following chemotherapy.⁹³ Even disseminated and refractory malignant germ cell tumors may respond to aggressive chemotherapy⁹⁴ and salvage regimens involving bone marrow transplantation.^{95,96}

Lymphoma

Lymphoma is an important cause of mediastinal mass, and is distinguished from other mediastinal lesions in that management is primarily medical, not surgical. In most series, lymphoma represents between 10% and 20% of mediastinal masses in both adults and children.^{6-8,63} Lymphomas are the most common anterior and middle mediastinal masses in children; a majority of pediatric patients with *Hodgkin lymphoma* (HL) and half of those with *non-Hodgkin lymphoma* (NHL) present with a mediastinal mass.⁹⁷ HL has a bimodal distribution, arising in adolescents and young adults as well as in those older than 50, whereas NHL arises most commonly in older adults.

Primary mediastinal B-cell lymphoma (PMBL) is a distinct subset of NHL that has a similar clinical presentation as classic HL of the nodular sclerosing subtype.⁹⁸ Both present in the third or fourth decade of life and tend to affect females. These tumors present as a bulky anterior mediastinal mass involving the thymus (see Fig. 83-6). SVC syndrome is a common presentation of PMBL, less so for HL (see Video 83-2 and eFig. 83-2), which can involve the hilar nodes and lung parenchyma.⁹⁹ However, there are distinct and nonoverlapping histologic features. HL is characterized by the Hodgkin/Reed Sternberg cell in a nodular growth pattern with a specific immunophenotype of CD30+, CD45-, and CD15+ in 85% of cases. PMBL is histologically characterized by an infiltrate of large cells in a diffuse pattern with an immunophenotype of a mature B lymphocyte expressing CD20. A B-cell lymphoma that exhibits histologic features of both PMBL and HL has been named "gray zone lymphoma."¹⁰⁰

Distinguishing HL from PMBL is important for guiding therapy, thus tissue biopsy is indicated. The current stan-

dard of treatment for early stage, bulky mediastinal disease is combined modality therapy, consisting of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) and radiation. Optimal therapy for nonbulky mediastinal HL is controversial; recent clinical trials suggest no difference in overall survival but an increase in risk for disease progression with chemotherapy alone.^{101,102} The benefits of radiation therapy must be balanced with the risk for serious late complications, including pulmonary fibrosis, cardiovascular disease, and secondary malignancies such as breast and lung cancer.¹⁰⁰

PMBL is treated with immunochemotherapy, which includes rituximab with CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone)-based regimens, followed by radiation. Whereas these standard dose regimens have a cure rate of up to 75%, more recent evidence has shown that dose intensity may improve outcomes in PMBL. DA-EPOCH (dose-adjusted etoposide, vincristine, doxorubicin, cyclophosphamide, prednisone, rituximab) has been shown to confer an overall survival of 97% without the need for radiation treatment in the majority of patients.¹⁰³ The prognosis of HL and NHL has improved strikingly in the past 2 decades as staging of the disease has been refined and as more effective and less toxic combinations of radiotherapy and chemotherapy have evolved. With new chemotherapy regimens, radiotherapy may not be a necessary part of the treatment plan for PMBL.^{103a} PET scan, which is often used to restage aggressive lymphomas, appears to have a high negative predictive value and may be helpful for clinicians in deciding when to omit radiotherapy after primary chemotherapy; this is being investigated in an ongoing clinical trial.^{103b,103c} Effective salvage regimens including bone marrow transplantation have been developed to treat relapsed disease. HL is curable in approximately 75% of patients, although late toxicities of treatment contribute significantly to mortality.

Thyroid Lesions

In surgical series, ectopic thyroid glands account for fewer than 10% of mediastinal masses but, in clinical practice, these are probably more common. Thyroid tissue within the mediastinum is of two distinct origins. Most commonly, a cervical goiter extends subternally into the anterior mediastinum.¹⁰⁴ Primary intrathoracic goiter, presumably originating from an embryonic nest of heterotopic thyroid tissue, is rare. Most such goiters are in the anterior mediastinum, but they may arise in the middle or posterior mediastinum as well.^{6,7} Intrathoracic goiter presents predominantly in middle aged or older women. Although it is usually asymptomatic, goiter may cause hoarseness, cough, or swelling of the face and arms. Intrathoracic thyroid tissue is easily recognized by radioactive iodine scanning,¹⁰⁵ as long as the scan is completed before intravenous iodinated contrast injection, which may block iodine uptake for weeks. It may be suspected on the basis of high radiodensity on CT scans, particularly after iodinated contrast injection.^{106,107} Treatment is surgical resection.

Parathyroid Lesions

Mediastinal parathyroid tissue accounts for up to 10% of cases of hyperparathyroidism, and the mediastinum is the most common site for ectopic parathyroid adenomas in

surgically resistant hyperparathyroidism.¹⁰⁸ Half of ectopic parathyroid adenomas lie in the anterior mediastinum, usually near the thymus. Parathyroid cysts may enlarge sufficiently to appear as a mass on the chest radiograph and to produce symptoms, but ectopic tissue may be difficult to locate.¹⁰⁹ Evaluation of the lesion is typically conducted using CT angiography, ultrasound, MRI, and the sensitive technetium-99m sestamibi scanning.¹¹⁰ Selective arteriography and venous sampling for parathormone levels have largely been supplanted by sestamibi radionuclide scanning.¹¹⁰ Parathyroid adenomas are cured by complete resection, and resection via VATS is increasingly advocated.⁵⁵ Parathyroid carcinoma may be functional, resulting in varying degrees of hyperparathyroidism, but is also locally invasive and may metastasize.¹¹¹ Cure is possible with aggressive surgical management¹¹² that may be guided by imaging and functional localization studies.¹¹³

Mesenchymal Tumors

Included in this group of unusual mediastinal masses are lipomas, fibromas, mesotheliomas, and lymphangiomas (see Table 83-4).⁶ They arise from connective tissue, fat, smooth muscle, striated muscle, blood vessels, or lymphatic channels and can be found in any region of the mediastinum. Histologically and clinically, they are not substantially different from their counterparts elsewhere in the body. Unless the lesion is very large, the presence of symptoms usually indicates that the lesion is malignant.^{6,17}

Lipoma is the most common mesenchymal tumor of the mediastinum and is most often located in the anterior mediastinum. It may be encapsulated or unencapsulated, appearing as a smooth and rounded lesion with well-defined margins. The characteristic low density of lipomas on CT images (Fig. 83-11) permits a confident diagnosis unless there is associated heterogeneity, invasion of surrounding tissues, or poor demarcation of the mass's perimeter, in which case malignancy (liposarcoma or lipoblastoma) or teratoma must be excluded.¹⁷ Considerably more common than lipoma is mediastinal lipomatosis, or generalized overabundance of histologically normal unencapsulated fat (see Fig. 83-2).¹¹⁴ Mediastinal lipomatosis appears on the conventional radiograph as a smooth widening or bulging of normal mediastinal contours, and its low homogeneous CT density confirms the diagnosis.¹⁷ Mediastinal lipomatosis does not compress or displace other mediastinal structures.

Sarcomas involving the mediastinum are rare but, if present, are likely to be due to nerve sheath sarcoma, spindle cell sarcoma, leiomyosarcoma, or liposarcoma.¹¹⁵ Prior radiation therapy appears to be a predisposing factor in some cases.¹¹⁶ Primary mediastinal sarcoma is a rare entity that affects adults; it can present with distant metastases¹¹⁷ and tends to have an aggressive course.

Primary Carcinoma

Numerous rare neoplasms of the mediastinum have been described in larger case series of mediastinal tumors as well as in isolated case reports.^{7,118} Case series up through the 1980s report primary carcinoma of the mediastinum as comprising 1% or fewer of the cases of malignant neoplasms found in the anterior mediastinum.^{59,143} Since these case series, very little regarding primary carcinoma of the

Figure 83-11 Lipoma. **A**, Chest radiograph of a 31-year-old man showing an abnormality at the right cardiophrenic angle noted as an incidental finding. **B**, Axial chest CT demonstrates a well-circumscribed homogeneous fat-density mass characteristic of a mediastinal lipoma extending into the right hemithorax (arrow).

mediastinum as a specific disease has been reported. It is possible that these tumors represented a heterogeneous group of metastatic carcinoma of unknown origin, or otherwise unclassifiable disease.

In the 1990s, cases of young patients with a highly aggressive carcinoma presenting in the mediastinum and other midline structures were reported; these tumors were found to have t(15;19) translocations, resulting in a *BRD4-NUT* fusion oncogene,^{119,120} which was first described in 2003. These NUT midline carcinomas are uniformly fatal, presenting as large masses with local mass effects and distant metastases. The advent of molecular targets in cancer treatment make this discovery a potential

Figure 83-12 Simplified schematic diagram depicting mediastinal lymph node groups. (Redrawn from McLoud TC, Meyer JE: Mediastinal metastases. *Radiol Clin North Am* 20:453–468, 1982.)

therapeutic target in undifferentiated or poorly differentiated epithelioid malignancies.

LESIONS OF THE MIDDLE MEDIASTINUM

Enlargement of Lymph Nodes

Numerous classifications exist for the mediastinal lymph nodes, including the most recently accepted classification by the International Association for the Study of Lung Cancer.¹²¹ Figure 83-12 presents a simplified grouping of the main mediastinal nodes that corresponds to findings on chest radiography and CT scans.¹²² Most authors consider 1-cm diameter at the short axis to be the upper limit of normal.¹⁸

Evaluating the mediastinum in the context of staging lung cancer is discussed elsewhere in the textbook (see Chapter 53). Mediastinal lymph node enlargement is most often due to lymphoma,¹²³ metastatic cancer,¹²² granulomatous inflammation, such as that caused by sarcoidosis, or infection. Infection should be considered when the adenopathy is associated with a pulmonary opacity. Tuberculosis is a notable cause of mediastinal adenopathy that can mimic sarcoidosis or malignancy and should be suspected in a host with known tuberculosis risk factors, such as recent known exposure or residence in an endemic area.¹²⁴ Fungal infections that cause granulomas, particularly histoplasmosis, may present with mediastinal and hilar adenopathy in the absence of a pulmonary opacity.¹²⁵

Numerous less common causes of mediastinal adenopathy are described, including Castleman disease or angiofollicular lymphoid hyperplasia. Mediastinal adenopathy is common in HIV-infected patients and is usually caused by infection, although adenopathy may also be caused by lymphoma, Kaposi sarcoma, and other noninfectious processes.¹²⁶

Developmental Cysts

Developmental cysts of various sorts comprise 10% to 20% of all mediastinal masses.^{6,127} Most can be identified as bronchogenic, enteric, or pericardial.⁶ Bronchogenic and enteric cysts are often referred to as *foregut duplication cysts* because of their origin from aberrant portions of the ventral and dorsal foregut, respectively.

Bronchogenic cysts are found near large airways, often just posterior to the carina (Fig. 83-13), although they may be attached to the esophagus or even lie inside the pericardial space.⁶ The cyst wall often contains cartilage and respiratory epithelium. Most are discovered incidentally and cause no symptoms; however, they may communicate with the tracheobronchial tree and become infected¹²⁸; enlarge sufficiently to cause airway obstruction,¹²⁹ pulmonary artery compression,¹³⁰ or hemodynamic collapse¹³¹; or rupture.¹³² Enteric or enterogenous cysts are similar in location and appearance to bronchogenic cysts, but have digestive tract epithelium. They are relatively uncommon in adults, but are the most common cysts found in infants and children, in whom they may be associated with spinal extension and malformations of the vertebral column (called “neurenteric” cysts). Enteric cysts can occasionally be multiple and associated with duplications of other portions of the gastrointestinal tract.

Pericardial cysts account for about one third of cystic masses in adults, but are much less common in children (see Table 83-5). They lie against the pericardium, diaphragm, or anterior chest wall in the right cardiophrenic angle. Rarely, pericardial cysts may communicate with the pericardial space. Although typically harmless, pericardial cysts may enlarge enough to cause right ventricular outflow obstruction,¹³³ or they may rupture and hemorrhage to cause pericardial tamponade¹³⁴ or sudden cardiac death.¹³⁵

Developmental cysts can usually be identified by CT (see Fig. 83-13A) or ultrasonography, and the diagnosis may be confirmed by aspiration cytology. MRI is valuable for confirming the cystic nature of these lesions (see Fig. 83-13B-D). Pericardial cysts can be followed with serial imaging and need not be resected unless they cause symptoms. Bronchogenic cysts can also be followed conservatively if asymptomatic¹³⁶; however, most authorities favor resection for purposes of diagnosis and to reduce the potential for complications.^{128,132} Alternatives to thoracotomy include therapeutic aspiration^{137,138} and thoroscopic or mediastinoscopic excision.^{56,139,140}

LESIONS OF THE POSTERIOR MEDIASTINUM

Neurogenic Tumors

The vast majority of tumors in the posterior mediastinum represent neoplasms arising from neural tissues,^{6,7} historically accounting for about 20% of adult cases and twice that proportion in children (see Table 83-5). Neurogenic tumors appear radiographically as a unilateral paravertebral mass.^{6,141,142} Clinical manifestations include chest pain from nerve or bone erosion, dyspnea secondary to tracheal compression, and neurologic deficits resulting from spinal cord compression by intraspinal tumor extension. In addition, many neurogenic tumors are hormonally active. MRI

Figure 83-13 Bronchogenic cyst. Axial unenhanced chest CT (**A**) shows a mildly hyperattenuating structure (*arrow*) in the subcarinal space. Axial triple inversion-recovery (TIR) MRI (**B**) and axial unenhanced double inversion-recovery (DIR) image (**C**) show the same lesion (*arrows*). Note the very high signal on the fluid-sensitive TIR image (**B**), consistent with fluid, and the mildly increased signal on the unenhanced DIR image (**C**), consistent with proteinaceous or hemorrhagic fluid; the latter mechanism also accounts for the hyperattenuating appearance on CT. Enhanced DIR MRI (**D**) shows no enhancement of the lesion (*arrow*) following intravenous gadolinium administration, typical of a foregut duplication cyst. (Courtesy Michael Gotway, MD.)

is usually indicated when there is suspicion for a neurogenic lesion. Although the majority of neurogenic tumors are benign, surgical resection is indicated to alleviate local symptoms from mass effects of the tumor.

Neurogenic tumors are classified by site of origin: peripheral nerves, sympathetic ganglia, or paraganglionic tissue (Table 83-6). Tumors arising from peripheral nerves include neurofibromas, neurilemmomas, and neurosarcomas. Neurofibromas contain both nerve sheath cells and nerve elements and are the most common tumor of this group. They are incompletely encapsulated and may grow quite large, producing symptoms by compression of nerves or other structures. Mediastinal neurofibroma may be one manifestation of von Recklinghausen disease (neurofibromatosis). As with these tumors found elsewhere in the body, neurofi-

bromas may eventually transform into the malignant neurosarcoma in 10% to 15% of patients.⁷

Neurilemoma, or schwannoma (Videos 83-11A and B, and eFig. 83-43), is another common neurogenic tumor that arises from the neural sheath. Most often seen in the third to fifth decade of life, neurilemoma usually causes no symptoms and appears as a well-circumscribed, homogeneous density on chest radiography (Fig. 83-14A).^{6,7} It is always completely encapsulated and does not invade surrounding tissues, although neurilemmomas may extend into intervertebral foramina (Fig. 83-14B and C). Treatment of both neurilemoma and solitary neurofibroma is resection.

Malignant tumors of nerve sheath origin are also known as malignant neurofibroma, malignant schwannoma, or neurogenic fibrosarcoma. These tumors behave aggressively, with both local invasion and distant metastasis. Half arise in patients with neurofibromatosis.¹⁵ Treatment requires wide excision and usually adjuvant radiation.¹⁵

Tumors arising from nerve cells in sympathetic ganglia generally affect children and display a spectrum of neoplastic behavior ranging from ganglioneuroma, a benign tumor, to the malignant tumors ganglioneuroblastoma and neuroblastoma. Ganglioneuromas cause symptoms merely by mass effect, and are usually cured by surgical excision. Ganglioneuroblastomas have intermediate behavior and can invade locally but are less likely to metastasize.⁷ Neuroblastoma rapidly displaces and invades adjacent structures and may be widely metastatic at the time of presentation.^{143,144} These tumors often elaborate endocrine peptides and

Figure 83-14 Series of imaging studies of a 64-year-old asymptomatic man with a surgically proved neurilemoma, or schwannoma. **A**, Frontal chest radiograph showing an incidental finding of a discrete mass behind the right clavicular head (arrow). **B**, Axial chest CT showing homogeneous, well-circumscribed appearance and posterior location adjacent to the vertebral column. **C**, Magnetic resonance image showing extension of the tumor into the intervertebral foramen (arrow).

catecholamines, and are associated with diarrhea, fever, anorexia, and weight loss.⁶ The propensity to produce catecholamines is used to advantage by promoting tumor uptake of the catecholamine precursor ¹²³I- or ¹³¹I-*meta*-iodobenzylguanidine (MIBG) for purposes of diagnosis, identification of distant tumor metastases, and treatment.^{145,146} Treatment of neuroblastoma involves using escalating multimodality therapy strategies that are based on the risk for disease progression.¹⁴⁷

Neoplasms arising from paraganglionic or chemoreceptor tissue include pheochromocytomas, which are found rarely in the mediastinum and are indistinguishable clinically and histologically from their counterparts in the abdomen, and paragangliomas (chemodectomas). Paragangliomas may secrete catecholamines just as do pheochromocytomas and thus may also be detected and perhaps treated with MIBG.¹⁴⁸ They appear benign under the microscope and seldom metastasize, but spread locally in an aggressive fashion and thus have high morbidity and mortality rates.⁶

MISCELLANEOUS MEDIASTINAL MASSES

Benign Lesions

Pancreatic pseudocysts may extend into the mediastinum, usually through the aortic or esophageal hiatus.^{7,149,150} They have been reported in all three mediastinal compartments. Hydatid cysts also arise rarely in the mediastinum.⁷ The posterior mediastinum is occasionally the site of a thoracic duct cyst.^{6,63} Also, extramedullary hematopoiesis (Video 83-12 and eFigs. 83-44 and 83-45) in patients with chronic hemolytic anemia may appear as a mediastinal mass, often in a posterior location. Meningoceles, outgrowths of the spinal meninges that protrude along the course of a spinal nerve, can produce posterior mediastinal masses.

Vascular Masses and Enlargements

Although not technically masses, a variety of vascular lesions must be considered in the differential diagnosis of a mediastinal mass seen on the chest radiograph.^{7,151} These include poststenotic aortic dilation, aneurysms (Video 83-13 and eFig. 83-46) or tortuosity of the aorta

and great vessels, aortic coarctation, innominate vein and SVC aneurysm, persistent left vena cava, azygos (Video 83-14 and eFig. 83-48) and hemiazygos vein enlargement, anomalous pulmonary venous return, pulmonary venous varix, and varices associated with portal hypertension (eFig. 83-49).¹⁵² Idiopathic dilation of the pulmonary trunk and pulmonary arterial hypertension of any cause may appear as a mediastinal mass, and traumatic aortic transection or more subtle vascular injuries may result in mediastinal hematoma.

Angiography has been the traditional means of diagnosing mediastinal masses of vascular origin but, in most cases today, CT imaging with intravenous contrast provides a more convenient diagnosis.^{153,154} MRI may permit definitive diagnosis without radiation or contrast exposure.

Diaphragmatic Hernia

Omental fat (Video 83-15 and eFig. 83-50; see also Video 83-6 and eFig. 83-12) or other abdominal contents may protrude through the diaphragm via several potential routes, producing mediastinal mass lesions in any compartment.¹⁷ A hernia through the foramen of Morgagni (eFig. 83-50) produces a cardiophrenic angle mass, usually on the right side in the anterior mediastinum. Bochdalek hernia (eFig. 83-51), in the posterior mediastinum, generally appears on the left side, presumably because the liver prevents herniation on the right. Herniation of fat around the esophagus is believed to precede hiatal hernia formation; either may appear as a mediastinal mass on chest radiography. Fine linear opacities are often demonstrable in diaphragmatic fat herniations on CT imaging. These are thought to represent omental vessels within the hernia, and they may help differentiate a hernia from a lipoma.¹⁷

GENERAL APPROACH TO A MEDIASTINAL MASS

INITIAL EVALUATION

With the advent of advanced imaging techniques such as CT, MRI, and nuclear imaging, the evaluation of a mediastinal mass is best made in a multidisciplinary setting

involving the pulmonologist or internist, a radiologist, and a thoracic surgeon. The differential diagnosis of a mediastinal mass depends significantly on patient demographics, the presence of clinical symptoms, as well as the anatomic location, size and morphology. For a mediastinal mass that is found incidentally, the primary concern for a clinician is to determine whether it is benign or malignant, and, if benign, whether it has the potential to cause local symptoms. At a minimum, a chest CT scan with contrast should be obtained to evaluate any mediastinal mass detected by conventional radiography. This narrows the differential diagnosis and suggests further imaging or a diagnostic and/or therapeutic procedure. A stable appearance, in comparison to older films, can obviate the need for further investigation in selected patients. A few benign lesions in the mediastinum can be diagnosed with confidence based on clinical information and CT scan appearance; such benign lesions include vascular lesions, extramedullary hematopoiesis, pericardial cysts and developmental cysts, and mediastinal lipomatosis. Suspected mediastinal thyroid tissue can be confirmed by radioactive iodine scans.

SURGICAL MANAGEMENT

In most cases, the optimal diagnostic and therapeutic maneuver is surgical resection of the mass.¹⁵⁵ The decision to perform a biopsy versus resection is thus based on the presumptive diagnosis after imaging. A suggested approach for evaluation is shown in Figure 83-15.

In the anterior mediastinum, well-encapsulated lesions are resected, whereas biopsy will be performed in those situ-

ations where there is a high degree of suspicion for lymphoma. Biopsy is also preferred for locally invasive or frankly unresectable anterior mediastinal lesions. Biopsy options for anterior lesions include CT-guided needle biopsy and anterior mediastinotomy. Cervical mediastinoscopy is less useful for anterior mediastinal masses because the anterior mediastinal mass is not near the pretracheal plane. Interventions by VATS are generally reserved for those lesions that are amenable to resection. Definitive resection of anterior mediastinal masses can be performed by VATS, median sternotomy, or a transcervical approach (e.g., Cooper thymectomy). A robotic VATS approach has gained in popularity in recent years for resection of anterior mediastinal masses.

In the middle mediastinum, the majority of masses in adults are malignant, the most common being lymphoma or metastatic disease. Hence for lesions in the middle mediastinum, biopsy is the typical initial approach. Biopsy can be performed by either CT-guided needle techniques, EBUS or EUS-TBNA, or by mediastinoscopy or VATS. Given the proven sensitivity and negative predictive value of EBUS-TBNA, this is the preferred sampling option. When benign-appearing cystic lesions are found by diagnostic imaging, the lesion is removed by either VATS or open thoracotomy.

In the posterior mediastinum, most lesions are resected either with a VATS or thoracotomy approach. A thoracotomy is preferred if there is any suggestion of malignancy (to ensure free resection margins), size greater than 5 cm, or presence of inflammation or infection that can obscure dissection planes. Surgical experience plays a large part in determining the technique utilized for intervention.

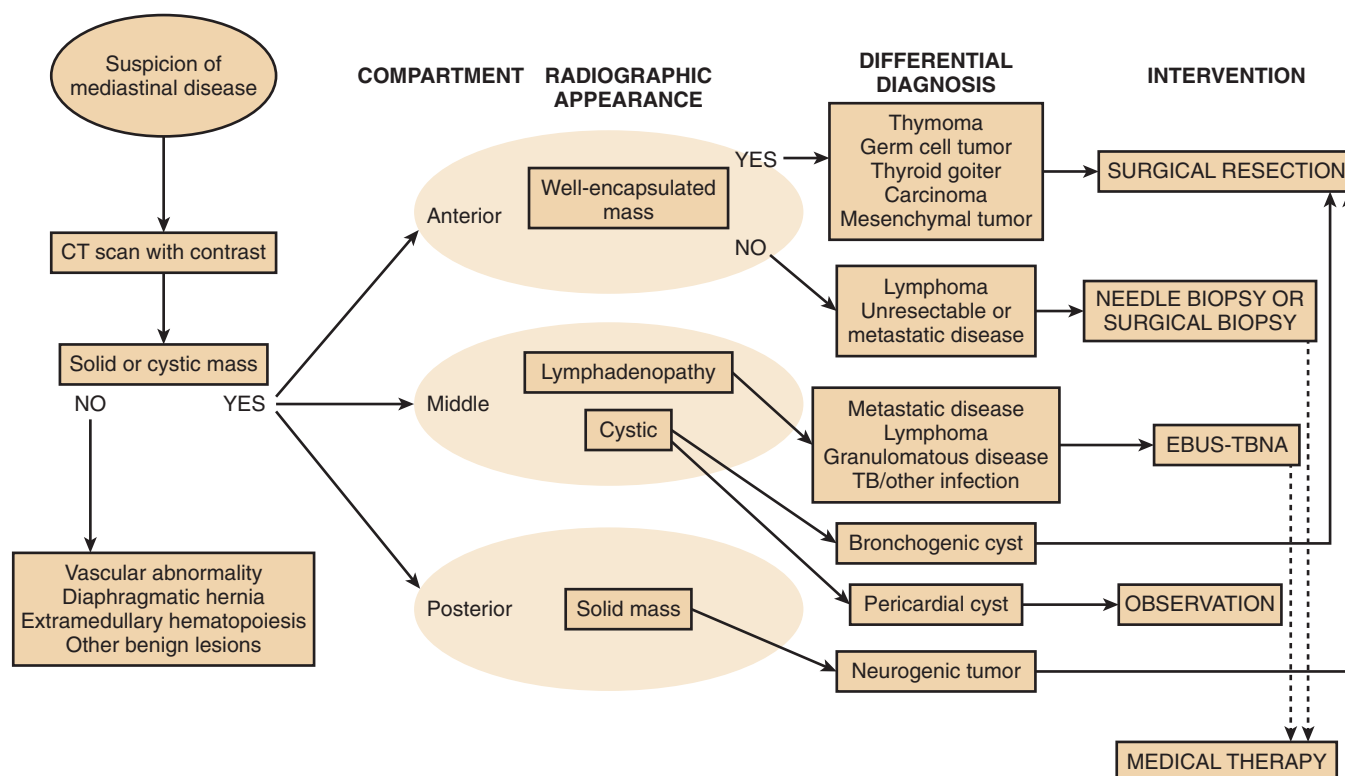

Figure 83-15 A suggested algorithm for the diagnostic approach to mediastinal masses.

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of David J. Pierson, MD, who wrote this chapter for the first and second editions, and coauthored this chapter with DRP for the third edition. These earlier chapters contain more extensive and historical references.

Key Points

- The mediastinum, which contains thoracic viscera in the center of the chest, can be divided into three compartments based on anatomic boundaries that can be seen on a lateral chest radiograph: anterior, middle, and posterior.
- While the majority of mediastinal masses are benign, the likelihood of a mediastinal mass being malignant depends on the compartment of the mediastinum, patient factors, and the presence of symptoms. Symptomatic masses are more likely to be malignant.
- The most common mediastinal masses in the anterior compartment include thymomas, germ cell tumors, and lymphoma. The middle compartment includes lymphadenopathy and benign developmental cysts. Isolated mediastinal adenopathy may represent sarcoidosis, tuberculosis, lymphoma, lung cancer, or metastatic disease from an extrathoracic malignancy. The posterior compartment includes mainly neurogenic tumors.
- Most mediastinal tumors and cysts should be surgically removed due to potential for malignancy and local compressive and invasive effects on adjacent vital structures.

eFigure 83-14 Neurogenic tumor on magnetic resonance (MR) imaging. Axial thoracic T1-weighted (**A**), T2-weighted (**B**), coronal enhanced T1-weighted (**C**), and sagittal unenhanced T1-weighted (**D**) MR images show a neurogenic tumor (*arrows*). Note the tumor extension from the neural foramen (*arrowheads*). The lesion shows increased signal on T2-weighted images (**B**) and intense contrast enhancement (**C**). (Courtesy Michael Gotway, MD.)

eFigure 83-15 Utility of magnetic resonance imaging (MRI) for determining mediastinal involvement in bronchogenic malignancy. **A**, Axial unenhanced chest CT shows a medial right upper lobe bronchogenic malignancy (*arrow*, **A**) with extensive contact with the mediastinum, especially the right brachiocephalic vein (*arrowhead*, **A**). **B**, Axial thoracic steady-state free precession, unenhanced (**C**) and enhanced (**D**) T1-weighted MRI shows extension of the neoplasm (*arrows*, **B–D**) into the mediastinal fat with invasion of the right brachiocephalic vein, evidenced by the small intravascular nodule (*arrowheads*, **B–D**). See [Video 83-8](#) for the full study of part **B**. (Courtesy Michael Gotway, MD.)

eFigure 83-16 Typical appearance of thymoma at thoracic imaging. Frontal (A) and lateral (B) chest radiographs show a smoothly circumscribed mediastinal mass (arrows) at the level of the junction of the heart and great vessels. The obscuration of the right heart border on the frontal projection (A) and the presence of the mass overlying the heart on the lateral projection (B) indicates that the mass is adjacent to the heart. C, Axial enhanced chest CT shows the smoothly circumscribed, enhancing mediastinal mass. Axial T1-weighted (D) T2-weighted (E), enhanced, fat saturation T1-weighted (F), and coronal T1-weighted (G) images show the mediastinal lesion (arrows) to advantage. In particular, the indolent nature of the mass, evidenced by the maintained fat plane between the mass and pericardium (arrowheads, G) is well shown. The lesion shows intermediate-to-slightly-decreased signal on T2-weighted imaging (E), consistent with the cellular nature of the neoplasm. (Courtesy Michael Gotway, MD.)

eFigure 83-17 Cystic degeneration within a thymoma. Axial enhanced chest CT shows an enhancing anterior mediastinal mass containing internal low attenuation (*arrowheads*) consistent with cystic change or necrosis. (Courtesy Michael Gotway, MD.)

eFigure 83-18 Utility of chest CT for thymic neoplasm staging. A–D, Axial enhanced chest CT shows a lobulated mass (*large arrows, A–D*) with foci of calcification (*arrowheads, C and D*). The CT scan shows features consistent with an aggressive neoplasm, including lobulation, mediastinal fat infiltration, regional lymphadenopathy (*double arrowhead, B*), and marked vascular compression (*small arrows, A and C*). Compare the appearance of this aggressive neoplasm with the more indolent lesion shown in e-Fig. 83-16. (Courtesy Michael Gotway, MD.)

eFigure 83-19 Utility of chest CT for thymic neoplasm staging. Axial chest CT shows a circumscribed anterior mediastinal mass (*arrow*) in contact with the pericardium. While the circumscribed nature of the lesion initially suggests a relatively indolent neoplasm, potentially amenable to surgical resection, chest CT also shows pleural nodules (*arrowheads*) in the left lower medial thorax, representing intrathoracic metastatic disease. (Courtesy Michael Gotway, MD.)

eFigure 83-20 Limited utility of ^{18}F FDG-PET for thymic neoplasm evaluation. **A**, Axial unenhanced chest CT shows an anterior mediastinal mass (*arrow*) consistent with a thymic neoplasm; note calcification within the lesion. **B**, ^{18}F FDG-PET image shows modest glucose utilization within the tumor (*arrow*), but the degree of tracer uptake does not exceed that of mediastinal blood pool (*arrowheads*). In general, tracer activity must exceed that seen within mediastinal blood pool to confidently suggest a malignant process. (Courtesy Michael Gotway, MD.)

Figure 83-21 Thymic neoplasm recurrence. Frontal chest radiograph (A) and enhanced chest CT (B) at presentation show a left-sided mediastinal mass (arrows) subsequently shown to represent thymic neoplasia; note the lobulation, cystic change (*), vascular compression and displacement, and calcification (arrowhead) on CT scan (B), all suggestive of an aggressive neoplasm. C, Frontal chest radiograph performed months following resection of the thymic neoplasm shows a new lesion abutting the posterior mediastinal surface of the left superior thorax (C, arrowhead), consistent with tumor recurrence. D, Frontal chest radiograph several months following C shows an enlarging mediastinal mass (double arrowheads) and enlarging pleural metastatic deposits (arrow, D).

eFigure 83-21, cont'd E and F, Enhanced chest CT confirms pleural metastatic disease (*arrows*). (Courtesy Michael Gotway, MD.)

eFigure 83-22 Chest CT scan of thymic carcinoma. Focused axial enhanced chest CT shows a lobulated anterior mediastinal mass with foci of stippled calcification and extensive contact between the mass and vessels, in particular with obliteration of the fat plane between the mass and main pulmonary artery. (Courtesy Michael Gotway, MD.)

eFigure 83-23 Neuroendocrine thymic malignancy (“thymic carcinoid tumor”). **A**, Frontal chest radiograph shows a smoothly circumscribed left-sided anterior mediastinal mass. **B**, Axial enhanced chest CT scan shows a solid, homogeneously enhancing left-sided anterior mediastinal mass with contralateral mediastinal shift, but no other overtly aggressive features. Axial double inversion recovery T1-weighted (**C**) and T2-weighted (**D**) magnetic resonance images also show the lesion and its mass effect, but no locally invasive behavior. The T2-weighted (**D**) image shows intermediate signal within the lesion, indicative of a relatively cellular neoplasm. The small “black dot” anterior and medial to the mass represents a flow void within an enlarged mediastinal vein. **E** and **F**, Intraoperative view of the lesion during resection shows the large vein on the surface of the neoplasm; this vascular pedicle (arrows, **F**) was identified at surgery and ligated. **G**, Photograph of the resected specimen. (A to D, Courtesy Michael Gotway, MD; E to G, intraoperative photographs courtesy Andrew H. Goldstein, MD.)

eFigure 83-24 Hodgkin lymphoma involving the thymus. **A**, Frontal chest radiograph shows a large left-sided anterior mediastinal mass. Axial (**B**) and coronal enhanced (**C**) chest CT scans show a minimally lobulated slightly inhomogeneous left-sided anterior mediastinal mass. The appearance is similar to thymic neoplasia. The pericardial effusion (*) and regional necrotic lymph node enlargement (arrowhead) are indicative of an aggressive process. (Courtesy Michael Gotway, MD.)

eFigure 83-25 Thymic "rebound" hyperplasia. **A**, Enhanced chest CT in a young patient with breast malignancy at time of diagnosis shows minimal soft tissue mixed with fat (arrows), consistent with normal residual thymus. **B**, Axial unenhanced chest CT shows marked increase in the soft tissue within the anterior mediastinum (arrows) several months following chemotherapy, consistent with "thymic rebound." The appearance can be difficult to distinguish from neoplasia. **C**, Enhanced chest CT 1 year after **B** shows return to a more normal appearance of the thymus (arrows). (Courtesy Michael Gotway, MD.)

eFigure 83-26 Thymic hyperplasia versus thymoma. **A**, Unenhanced chest CT in a patient with thymic hyperplasia shows a homogeneous low attenuation, smoothly circumscribed anterior mediastinal lesion (*arrow*) consistent with thymic hyperplasia; note the morphology of this lesion still resembles normal thymus. This appearance contrasts with **B**, the lobulated, irregular appearance of thymoma (*arrow*). (Courtesy Michael Gotway, MD.)

eFigure 83-27 Thymic cyst. **A**, Axial unenhanced chest CT shows a homogeneously (water density) low attenuation anterior mediastinal lesion (*arrows*). Note the cleft in the lesion (*arrowheads*); this morphology is reminiscent of the normal bilobed thymus. Coronal double inversion recovery unenhanced T1-weighted (**B**) and fast spin-echo T2-weighted magnetic resonance (**C**) images show low and high signal, respectively, within the lesion (*arrows*), consistent with fluid. This lesion has remained stable for a number of years. Both images show the cleft within the lesion (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 83-28 Teratoma. Frontal chest radiograph shows a large right-sided mediastinal mass, representing teratoma. (Courtesy Michael Gotway, MD.)

eFigure 83-29 Seminoma. **A**, Frontal chest radiograph shows a large right-sided mediastinal mass. **B–D**, Axial enhanced chest CT scans show a mildly inhomogeneous, lobulated mass (*arrows*) with compression and displacement of the right brachiocephalic vein (*arrowhead*), resulting in extensive azygos vein (*small arrows*, **B** and **C**) collateral circulation. See [Video 83-9](#) for the full study. (Courtesy Michael Gotway, MD.)

eFigure 83-30 Embryonal cell carcinoma. **A**, Frontal chest radiograph shows a circumscribed left-sided anterior mediastinal mass (*arrows*). **B-D**, Axial enhanced chest CT shows a heterogeneous anterior mediastinal mass that obliterates fat planes with the adjacent vessels. Internal low attenuation within the tumor, as seen in the example, is more commonly encountered as non-seminomatous mediastinal germ cell neoplasms than seminomas. See [Video 83-10](#) for the full study. (Courtesy Michael Gotway, MD.)

eFigure 83-31 Anterior mediastinal extension of a thyroid goiter. **A**, Frontal chest radiograph shows widening of the superior mediastinum with rightward shift of the trachea resulting from a mediastinal mass (*arrows*). The superior mediastinal widening extends into the base of the neck. **B–E**, Axial unenhanced chest CT shows enlargement of the cervical thyroid gland (*double arrowheads*, **A**). The anterior superior mediastinal mass (*arrows*, **C** and **E**) extends from the base of the neck, originating from, and in contact with, the cervical thyroid gland. The mass contains calcification (*single arrowhead*, **D**), a common finding in thyroid goiters. Continuity of a mediastinal lesion with the cervical thyroid gland is key for confidently establishing a mediastinal mass as thyroidal in origin. (Courtesy Michael Gotway, MD.)

eFigure 83-32 Ectopic mediastinal thyroid tissue. **A**, Planar frontal 99m-technetium sestamibi scintigraphy shows faint tracer uptake within the mediastinum (*arrow*), separate from the heart (H) and liver (L). Axial enhanced chest CT shows a heterogeneously enhancing anterior mediastinal mass (*arrow*). **C**, Axial CT image through the cervicothoracic junction shows absence of a normal thyroid gland (*arrowheads*, **C**). (Courtesy Michael Gotway, MD.)

eFigure 83-33 Middle mediastinal extension of a thyroid goiter. Axial enhanced chest CT shows a peripherally hyperenhancing mass with central necrosis posterior to the trachea. This lesion was in contact with thyroid tissue at the base of the neck, establishing it as mediastinal goiter extension. (Courtesy Michael Gotway, MD.)

eFigure 83-34 Ectopic anterior mediastinal parathyroid adenoma. Axial unenhanced (**A**) and axial (**B**), coronal (**C**), and sagittal (**D**) enhanced chest CT shows an intensely enhancing lesion (*arrow*) in the anterior mediastinum. **E**, Transverse sonography performed at the level of the suprasternal notch shows a hypoechoic nodule (*arrow*) corresponding to the CT abnormality. **F**, Planar frontal 99m-technetium sestamibi scintigraphy shows avid tracer accumulation within the anterior mediastinal lesion (*arrow*), confirming ectopic parathyroid adenoma. (Courtesy Michael Gotway, MD.)

eFigure 83-35 Mediastinal lymphangioma. Frontal chest radiograph in a 13-year-old boy shows a circumscribed left mediastinal mass without mediastinal shift. **B** and **C**, Axial enhanced chest CT shows an anterior and superior low attenuation mediastinal lesion surrounding, but not compressing, the left brachiocephalic vein (*arrows*); this behavior indicates that the lesion is relatively “soft.” Axial fat saturation T1-weighted (**D**) and T2-weighted (**E**) magnetic resonance images show a mass with heterogeneous signal intensity containing multiple fluid-fluid levels (*arrowheads*). The dependent signal within the areas of fluid-fluid level formation is bright on both T1- and T2-weighted images, consistent with blood. (Courtesy Michael Gotway, MD.)

eFigure 83-36 Anterior mediastinal lipoma. Axial enhanced chest CT shows an encapsulated fat-containing lesion (*arrow*) consistent with a small lipoma. (Courtesy Michael Gotway, MD.)

eFigure 83-37 Mediastinal liposarcoma. **A**, Axial chest CT shows a predominantly fatty attenuating mass, representing well-differentiated liposarcoma. **B**, Axial chest CT shows a mediastinal mass again containing fat, but with considerably more soft tissue than the well-differentiated lesion in **A**, representing moderately differentiated mediastinal liposarcoma. **C**, Axial chest CT shows a large inhomogeneous mass containing fat, but also with soft tissue components and extensive vascularity, representing poorly differentiated mediastinal liposarcoma. (Courtesy Michael Gotway, MD.)

eFigure 83-38 Mediastinal lipomatosis. **A**, Frontal chest radiograph shows widening of the superior mediastinum (*arrows*), but the contours of the mediastinum are not lobulated, nor is the mediastinum abnormally dense. **B–E**, Axial enhanced chest CT shows abundant, unencapsulated mediastinal fat (*) on both sides of midline, without significant nodularity. (Courtesy Michael Gotway, MD.)

eFigure 83-39 Mediastinal lymphadenopathy in a patient with sarcoidosis. A–F, Axial enhanced chest CT shows mildly enlarged lymph nodes in multiple mediastinal stations: **A**, highest right paratracheal nodes (station 1R, *arrow*); **B**, upper right paratracheal nodes (station 2R, *arrow*), **C–E**, lower right paratracheal nodes (station 4R, *arrows*); **D**, lower left paratracheal nodes (station 4L, *thin arrow*, **D**) and aortopulmonary window nodes (station 5, *arrowhead*, **D**); **F**, subcarinal nodes (station 7, *double arrowheads*, **F**). (Courtesy Michael Gotway, MD.)

eFigure 83-40 Angiofollicular lymphoid hyperplasia (Castleman disease). **A**, Frontal chest radiograph shows a right paratracheal mass in a patient with an anterior chest wall stab wound, with penetrating entry site on the skin marked by a paper clip. **B**, Axial enhanced chest CT shows an enhancing right paratracheal mass with small foci of calcification, shown to reflect angiofollicular lymphoid hyperplasia at surgical resection. **C**, Axial enhanced chest CT (**C**), T1-weighted (**D**) and T2-weighted (**E**) magnetic resonance images in a different patient show a posterior mediastinal mass (arrows) shown to reflect angiofollicular lymphoid hyperplasia at surgical resection. (Courtesy Michael Gotway, MD.)

eFigure 83-41 Growth of a bronchogenic cyst over time. **A**, Frontal chest radiograph shows a smoothly circumscribed lesion (*arrow*) in the left superior mediastinum. **B–D** Retrospective review of serial chest radiographs obtained over the previous 7 years shows slow enlargement of the lesion.

eFigure 83-41, cont'd E-J, Axial chest CT shows serial enlargement of the lesion over a 7-year period. (Courtesy Michael Gotway, MD.)

eFigure 83-42 Pericardial cyst. **A**, Frontal chest radiograph shows a smoothly circumscribed right cardiophrenic angle mass (*arrow*). **B**, Axial enhanced chest CT shows a homogeneous water density mass (*arrow*) abutting the right pericardium. Axial double inversion recovery T1-weighted (**C**) and axial triple inversion recovery (**D**) magnetic resonance images show fluid signal within the mass (*arrows*). Triple inversion recovery sequences (**D**) suppress fat signal, with water signal appearing bright (note the high signal of the cerebrospinal fluid posteriorly). The slight “shading” of the signal intensity posteriorly within the pericardial cyst may reflect debris or hemorrhage. (Courtesy Michael Gotway, MD.)

eFigure 83-43 Schwannoma. **A**, Frontal chest radiograph shows a smoothly circumscribed lesion (*arrow*) at the right thoracic apex. The extensive contact with the chest wall and lack of visualization of the superior border of the lesion (often referred to as the “incomplete border” sign) are consistent with a non-lung parenchymal origin. Axial (**B**) and coronal (**C**) enhanced chest CT shows a homogeneous low-attenuation lesion (*arrows*) in contact with the right superior mediastinum and chest wall. The lesion was shown to reflect schwannoma. See [Video 83-11](#) for the full studies. (Courtesy Michael Gotway, MD.)

eFigure 83-44 Extramedullary hematopoiesis. Enhanced chest CT in a patient with thalassemia shows enhancing paravertebral soft tissue (*arrows*), representing extramedullary hematopoiesis. (Courtesy Michael Gotway, MD.)

eFigure 83-45 Extramedullary hematopoiesis containing fat. **A**, Frontal chest radiograph in a patient with anemia shows an abnormal right-sided posterior mediastinal contour (*arrows*); a similar abnormal contour can be appreciated in the left retrocardiac region. The posterior mediastinal location is suggested by the relatively long contour abnormality without obscuration of the right heart border or lateral displacement of the right hilum. **B** and **C**, Axial enhanced chest CT shows bilateral posterior mediastinal masses (*arrows*) mixed with some areas of low attenuation, the latter consistent with fat. See [Video 83-12](#) for the full study. (Courtesy Michael Gotway, MD.)

eFigure 83-46 Mediastinal mass caused by aortic aneurysm. Frontal chest radiograph shows a huge left-sided mediastinal mass without visualization of a normal thoracic aorta. See [Video 83-13](#) for an enhanced chest CT showing a huge aneurysm of the descending thoracic aorta with mural thrombus. (Courtesy Michael Gotway, MD.)

eFigure 83-47 Mediastinal mass caused by superior vena cava aneurysm. **A**, Frontal chest radiograph shows a right-sided mediastinal mass (*arrow*). Patient had undergone Glenn shunt (SVC-to-PA) for double outlet right ventricle. **B**, Axial enhanced chest CT shows a 6-cm aneurysm of the superior vena cava (*arrow*). (Courtesy Michael Gotway, MD.)

eFigure 83-48 Mediastinal mass caused by enlargement of the azygos vein. **A**, Frontal chest radiograph shows a mass (*arrow*) in the right tracheobronchial angle; this is the normal position of the anterior portion of the azygos vein. **B–D**, Axial enhanced chest CT shows dense contrast enhancement of the enlarged azygos vein (*arrows*). See [Video 83-14](#) for the full study. (Courtesy Michael Gotway, MD.)

eFigure 83-49 Mediastinal mass caused by esophageal varices. **A**, Frontal chest radiograph shows bilateral paraspinal line displacement (*arrows*) consistent with a posterior mediastinal mass. **B**, Axial enhanced chest CT shows that the posterior mediastinal mass is caused by periesophageal varices (*arrows*). (Courtesy Michael Gotway, MD.)

eFigure 83-50 Foramen of Morgagni hernia. **A**, Frontal chest radiograph shows a smoothly circumscribed right cardiophrenic angle mass. Axial (**B-D**) and sagittal (**E** and **F**) enhanced chest CT scans show that the right cardiophrenic angle mass (*) contains fat and originates within the abdomen, herniating into the thorax through an anteromedial diaphragmatic defect (*arrowheads*, **D** and **F**). Note that vessels, seen as thin linear hyperattenuating streaks, can be seen accompanying the fat herniation (**D**). See [Video 83-15](#) for the full axial study. (Courtesy Michael Gotway, MD.)

eFigure 83-51 Foramen of Bochdalek hernia. Frontal (**A**) and lateral (**B**) chest radiographs show a smoothly circumscribed contour abnormality along the posterior left diaphragm (*arrow, B*). The finding is difficult to appreciate on the frontal chest radiograph (**A**), but is readily seen on the lateral projection (*arrow, B*). Axial (**C** and **D**) and coronal (**E**) unenhanced chest CT shows that the lesion (*) consists entirely of fat, originating from the abdomen and extending into the posteromedial thorax through a diaphragmatic defect (*arrow, C, and arrowheads, E*). (Courtesy Michael Gotway, MD.)

Mediastinal Fibrosis

INTRODUCTION

Pneumomediastinum and mediastinitis are disorders that involve the potential spaces and tissues of the mediastinum. Although both may be present at the same time, for example, after esophageal rupture, the term *pneumomediastinum* usually refers to the presence of aberrant air in the mediastinum without accompanying infection and *mediastinitis* refers to infection or inflammation regardless of the presence of air. These conditions are seen in a variety of unique clinical circumstances. Both tend to result from either breaches in the integrity of mediastinal structures or the spread to mediastinal structures from elsewhere in the body. Thus, anatomic considerations are similar for the two processes. However, the pathophysiology, clinical settings, management approaches, and clinical impact of pneumomediastinum and mediastinitis are quite different and are discussed separately.

GENERAL ANATOMIC CONSIDERATIONS

The mediastinum is traversed by the trachea and the esophagus, which are air-filled structures in direct communication with the outside world and may contain colonizing microorganisms. In addition, mediastinal lymph nodes drain the airways and lung parenchyma where inhaled organisms, antigens, and dusts are encountered. Consequently, entry of air or inflammatory and infectious materials into the mediastinum is readily accomplished by breaches in the integrity of these mediastinal structures or when materials deposited in the airways or distal lung are transported through the lymphatic system.

How air enters and moves through the mediastinum can be understood by referring to the soft tissue compartments of the neck, thorax, and abdomen, as illustrated in [Figure 84-1](#). The visceral space surrounding the trachea, esophagus, and great vessels in the neck continues into the chest to envelop the mediastinal viscera and passes through the diaphragm with the esophagus to communicate with the retroperitoneal space. This same space extends along the vessels and airways of the pulmonary hilum to merge with the distal bronchovascular sheaths (see [Fig. 84-1](#)).¹

Thus, it is possible for air or inflammation that reaches these tissue planes to dissect and spread to involve any of the mediastinal structures.

PNEUMOMEDIASTINUM

Pneumomediastinum consists of air or other gas in the mediastinum. Also known as *mediastinal emphysema*, it is one of several forms of aberrant extra-alveolar air that include subcutaneous emphysema, pulmonary interstitial emphysema, pneumopericardium, pneumoperitoneum, pneumoretroperitoneum, pneumocephalus, and pneumorachis (air in the spinal canal). Pneumothorax, the most common life-threatening form of extra-alveolar air, is discussed elsewhere (see Chapter 81).

Pneumomediastinum and subcutaneous emphysema were first recognized during childbirth. In her “Observations” of 1617 (as cited by Gordon²), Louise Bourgeois, midwife to the queen of France, wrote, “I saw that she tried to stop crying out, and I implored her not to stop, for fear that her throat might swell.” The first formal medical documentation of pneumomediastinum and subcutaneous emphysema during labor was by Simmons in 1784, and this association was reported in more than 130 patients by 1927.² Over the next 2 decades, Hamman^{3,4} had thoroughly established the clinical features of spontaneous pneumomediastinum and Macklin and Macklin⁵ had elegantly elucidated its pathophysiology. Little has been added to the pioneering descriptions of these investigators, but pneumomediastinum and other forms of extra-alveolar air are seen today in a greater variety of clinical circumstances. These include mechanical ventilation and other situations in critical care, decompression injury diving, chest trauma, and asthma.¹

PATHOPHYSIOLOGY

The pathophysiology of pneumomediastinum depends on the clinical circumstances in which it is encountered. Pneumomediastinum most commonly results from alveolar rupture but can also result from air escaping from the upper respiratory tract, intrathoracic airways, or gastrointestinal tract. Gas can be generated by certain infections, and outside air can reach the mediastinum after trauma or

Figure 84-1 Mediastinal compartments. Soft tissue compartments of the mediastinum (at levels of T2 and T5) in relation to those of the neck (at level of C7) and the upper abdomen (at level of L1) demonstrate continuity of the visceral space (shown in light green). A, aorta; E, esophagus; IVC, inferior vena cava; PA, pulmonary artery; SVC, superior vena cava; T, trachea. (Redrawn from Maunder RJ, Pierson DJ, Hudson LD: Subcutaneous and mediastinal emphysema: pathophysiology, diagnosis, and management. *Arch Intern Med* 144:1447–1453, 1984.)

surgery. These potential sources for mediastinal emphysema are summarized in [Table 84-1](#) and discussed in the following sections.

Air Originating from the Upper Respiratory Tract

Mediastinal air dissecting downward from the head and neck can originate in several ways. Retropharyngeal abscess is a long-established cause of gas in the neck, but other infections including dental abscess, cervical adenitis, salivary gland infection, tonsillitis, and osteomyelitis of the facial bones can also produce this finding.^{1,6} Odontogenic infections are said to be the most common of these.⁷

Dental extractions or drilling can be followed by pneumomediastinum. Passage of air into the soft tissues from the socket of an extracted tooth can be increased dramatically if positive pressure is applied at the mouth—as illustrated by the case of a soldier whose neck swelled on resumption of his duties as a bugler immediately after a tooth extraction.⁸

Injury to the paranasal sinuses, orbit, mandible, and other facial bones adjacent to the upper airways can provide access of air to the fascial planes of the neck, especially following nose blowing. Surgical procedures involving the upper respiratory tract may produce air in the neck via breaches in either the oropharyngeal mucosa or the trachea. For instance, pneumomediastinum and subcutaneous emphysema are common after tracheotomy; these findings were noted in 13% of cases in one prospective series in adults.⁹

Pneumomediastinum can also arise following traumatic attempts at endotracheal intubation or after overinflation of the endotracheal tube cuff when the hypopharyngeal mucosa or membranous trachea is injured ([eFig. 84-1](#)).¹⁰ Tracheal injury and esophageal rupture leading to pneumomediastinum can also happen when air is forced into the open mouth.^{11,12}

Air Originating from the Intrathoracic Airways

Blunt thoracic trauma, particularly deceleration injury as sustained in motor vehicle crashes, may lacerate or fracture the trachea or main bronchi and allow air to enter the mediastinum ([eFig. 84-2](#) and [Video 84-1](#); see [eFig. 76-10](#) and [Video 76-3](#)).¹³ Although the trachea may be damaged proximally, the majority of such injuries are within 3 cm of the carina, probably owing to the relative fixation of the airway at the carina and the development of a shearing force when the more mobile parts are displaced by the sudden impact.

Other potential sources of mediastinal air from the major intrathoracic airways include perforation by an aspirated foreign body and erosion by bronchogenic or esophageal neoplasm. Visceral perforation is associated more frequently with esophagoscopy than with bronchoscopy. However, the increasing use of bronchoscopic biopsy techniques and therapies for bronchial obstruction render this source for mediastinal air increasingly likely.

Air Originating in the Lung Parenchyma

Most instances of pneumomediastinum are the result of alveolar disruption. Alveoli may be disrupted after direct injury to the lung parenchyma, which allows air to escape from torn alveoli and terminal bronchioles, after surgery, when air can escape from cut surfaces, or when the lung is nicked in the course of central venous access procedures, or percutaneous or transbronchial lung biopsy. The majority of cases of alveolar disruption leading to pneumomediastinum, however, is from “spontaneous” alveolar rupture.

Mechanism of “Spontaneous” Alveolar Rupture. Disruption of alveolar walls and entry of air into the bronchovascular bundle can result when a pressure gradient becomes sufficient to disrupt the alveolar walls at their bases and force air into the pulmonary interstitium, as depicted in [Figure 84-2](#).^{1,5,14} Although it has been speculated that an increase in intra-alveolar pressure alone was

Table 84-1 Origins of Air in the Mediastinum**UPPER RESPIRATORY TRACT**

Head and neck infection (odontogenic, salivary glands, cervical adenitis, tonsillitis, peritonsillar abscess, osteomyelitis of facial bones)
 Fractures (involving paranasal sinuses, orbit, mandibles, other facial bones)
 Other mucosal disruption (trauma, surgery, attempted endotracheal intubation)
 Dental procedures (extractions, air-turbine drilling)

INTRATHORACIC AIRWAYS

Blunt or penetrating chest trauma
 Foreign body
 Iatrogenic (bronchoscopy, bronchial brushing, transbronchial biopsy, needle aspiration)
 Neoplasm

LUNG PARENCHYMA

Direct disruption of alveoli (penetrating trauma, surgery, transbronchial biopsy, needle aspiration)
 "Spontaneous" alveolar rupture (between alveolus and adjacent bronchovascular bundle)

GASTROINTESTINAL TRACT

Esophageal perforation
 Via pneumoperitoneum or pneumoretroperitoneum (gastric or intestinal perforation, diverticulitis, pneumatosis cystoides intestinalis, endoscopy, biopsy, infection)

EXTERNAL TO THE BODY

Penetrating trauma to neck or chest
 Surgical procedures (tracheotomy, mediastinoscopy, sternotomy)
 Via subcutaneous emphysema in association with chest tube insertion

INFECTION WITH GAS-PRODUCING ORGANISMS

Acute bacterial mediastinitis
 Head and neck infections

Figure 84-2 Extra-alveolar air movement into the bronchovascular bundle. Schematic diagram shows the mechanism of alveolar rupture across the bronchovascular sheath resulting from a pressure gradient between them. (Redrawn from Maunder RJ, Pierson DJ, Hudson LD: Subcutaneous and mediastinal emphysema: pathophysiology, diagnosis, and management. *Arch Intern Med* 144:1447–1453, 1984.)

capable of producing alveolar rupture, animal experiments have demonstrated that an increase in alveolar volume, due to increased *transpulmonary* pressure, is a more important determinant of disruption of the alveolar walls.¹⁵ This finding may explain the rarity of alveolar rupture following coughing and sneezing; contraction of muscles of the chest and abdominal walls counter the transient high intra-alveolar pressures, and transpulmonary pressures and alveolar volume do not increase.¹⁶

With decompression, when there are decreases in external pressure, high alveolar volumes undoubtedly contribute to alveolar rupture.^{16,17} The mechanism of alveolar rupture presumably relates to overdistention due to the expansion of gas trapped in the lungs during ascent.^{18,19}

Underlying disease of the lungs is probably also important. Pneumomediastinum and other forms of extra-alveolar air arising from the lung are almost always associated with parenchymal abnormalities in the affected lung both during mechanical ventilation^{16,20} and during spontaneous ventilation.^{1,5}

Spread of Air following Alveolar Rupture. Entry of air into the bronchovascular bundle, as depicted schematically in Figure 84-2, produces pulmonary interstitial emphysema (eFig. 84-3). This is the initial consequence of alveolar

rupture and may be the only overt manifestation of extra-alveolar air. According to Munsell,²¹ Laennec called this condition "interlobular emphysema." Because the mean pressure in the mediastinum, like that in the pleural space, is always somewhat negative with respect to the pressure in the pulmonary parenchyma, the pressure difference causes air to move toward the mediastinum.²² This is illustrated in Figure 84-3 and convincingly described in the 1944 paper by Macklin and Macklin,⁵ which first confirmed the sequence in experimental animals:

The first step ... was air passing through numerous minute ruptures in the strained bases of the alveoli of the overinflated region into the underlying vascular sheaths. The air bubbles, at the very first minute, moved along the vascular sheaths, coalescing and gaining in size. This streaming of air through the pulmonic interstitium reminded one of the flow of a river that ever increases in size by addition of new tributaries as it proceeds on its course. Reaching the root of the lung, the train of air bubbles passed into and distended the mediastinum. With continued insufflation an actual overflow into the retroperitoneum, anterior mediastinum and subcutaneous tissues of the root of the neck and axillae occurred. In extreme cases the mediastinal wall ruptured, producing a pneumothorax.

Figure 84-3 Extra-alveolar air movement throughout the body. The movement of air from alveoli to extra-alveolar sites showing the likely sequence for development of the different forms of extra-alveolar air following alveolar rupture.

These classic observations have since been confirmed in more recent studies but, conceptually, little has been added.

Entry of Air into the Pleural Space. Once in the mediastinum, air follows the path of least resistance and may rupture through the delicate mediastinal fascia and overlying pleura into the pleural space. This model is supported by observations that, in animal experiments, lower sustained inflation-hold pressures were required to produce pulmonary interstitial emphysema than to create a pneumomediastinum or pneumothorax and that, in most mechanically ventilated patients in one clinical series, pneumomediastinum preceded pneumothorax.²³ Another proposed mechanism for pneumothorax suggests that air dissects toward the periphery of the lung rather than toward the mediastinum and ruptures via subpleural blebs through the visceral surface of the lung. Which of these mechanisms most often accounts for “spontaneous” pneumothorax is uncertain.

Entry of Air into the Abdomen. Extra-alveolar air originating from disrupted alveoli may appear below the diaphragm as either pneumoperitoneum or pneumoretroperitoneum (eFig. 84-4).²⁴ To reach the retroperitoneal space, air from the mediastinum usually travels via the loosely packed paraesophageal connective tissue across the diaphragm. The retroperitoneal air may then break through the peritoneum to enter the peritoneal space.

Air Originating in the Gastrointestinal Tract

Mediastinal air can also originate from the gastrointestinal tract, either above or below the diaphragm. In *Boerhaave syndrome*, rupture of the esophagus allows air and other material to enter the mediastinum (eFig. 84-5).²⁵ In this circumstance, pneumomediastinum is accompanied by acute mediastinitis, as discussed later in this chapter. Pneumomediastinum can also result from esophageal perforation during upper gastrointestinal endoscopy²⁶ or following

the ingestion of a caustic such as paraquat²⁷ or lye (sodium hydroxide). Spontaneous pneumomediastinum is a rare presentation of achalasia.²⁸

Rarely, air or other gas originating in the retroperitoneal space can spread to the mediastinum.¹ Retroperitoneal causes of pneumomediastinum include perforation of a duodenal ulcer, ulcerative colitis, colonic diverticulitis (see eFig. 84-4), pneumatosis cystoides intestinalis, “rectal barotrauma”²⁹ and procedures such as sigmoidoscopy, colonoscopy, and barium enema.³⁰

Air Originating from External and Miscellaneous Sources

Pneumomediastinum can arise from air entering the body from external sources, particularly if positive pressure is applied at the subcutaneous tissue planes. Air can reach the mediastinum via the cervical soft tissues during tracheotomy,⁹ via the chest wall during arthroscopic shoulder surgery,³¹ or via the extremities as a result of industrial accidents.³² Mediastinal air can also arise from a pneumothorax by an unusual mechanism: air in the pleural space can reach the subcutaneous tissues via a tube thoracostomy tract, can dissect to the neck, and can then penetrate down into the mediastinum. Pneumomediastinum has also been observed following the insufflation of air into the peritoneal cavity for tuberculosis treatment,³³ during the course of modern era laparoscopy,³⁴ and via the female genital tract during pelvic examination,³⁵ douche,³⁶ postpartum exercise,³⁷ or blowing into the vagina,³⁸⁻⁴⁰ especially during pregnancy.⁴¹

Gas can form in the mediastinum during acute bacterial mediastinitis caused by gas-producing microbes. More commonly, however, pneumomediastinum associated with mediastinitis is due to communication with the gastrointestinal tract (as in Boerhaave syndrome), respiratory tract (as in necrotizing pneumonia), or outside air (as in traumatic or poststernotomy mediastinitis). These conditions are described in more detail later in this chapter.

CLINICAL SETTINGS AND SYNDROMES

Pneumomediastinum can be categorized as spontaneous or secondary. *Spontaneous* pneumomediastinum develops without an obvious etiology but may nonetheless have a predisposing condition or precipitating factor. Spontaneous pneumomediastinum is most frequently seen in young adults and is usually a benign, self-limited condition. In contrast, *secondary* pneumomediastinum arises from a specific pathologic event such as barotrauma from mechanical ventilation, intrathoracic or iatrogenic trauma, infection, or other acute conditions. Compared to spontaneous pneumomediastinum, secondary pneumomediastinum carries higher morbidity and mortality, likely due to the underlying etiology. Thus, in cases without an obvious precipitant, it is important to investigate for possible underlying causes of secondary pneumomediastinum (Table 84-2).⁴²

Spontaneous Pneumomediastinum

Predisposing Conditions. Underlying lung diseases are present in 25% to 44% of patients with spontaneous pneumomediastinum, as shown in two cohorts.^{42,43} Of those with lung disease, more than half had evidence of

Table 84-2 Spontaneous and Secondary Pneumomediastinum

Spontaneous	Secondary
VOLUNTARY ALTERATION IN BREATHING PATTERN	BAROTRAUMA
Marijuana smoking and cocaine inhalation	Mechanical ventilation
Pulmonary function testing	Noninvasive mechanical ventilation
Mountain climbing—"voluntary pressure breathing"	Manual ventilation during resuscitation, anesthesia, or transport
Wind instrument playing	Equipment malfunction or misconnection in anesthesia or oxygen therapy
Yelling, shouting, and singing	Heimlich maneuver
INVOLUNTARY ALTERATION IN BREATHING PATTERN	Deceleration injury
Childbirth	INVASIVE PROCEDURES
Vomiting	Esophageal perforation
Seizures; status epilepticus	Endobronchial needle aspiration

interstitial lung disease (eFig. 84-6). Other parenchymal diseases associated with pneumomediastinum include atelectasis,⁵ bronchiolitis,^{44,45} pneumonia,^{46,47} influenza,^{5,21} measles,⁴⁸ and hematogenous tumor metastases.⁴⁹

Obstructive lung diseases, especially acute asthma, are a well described predisposing factor leading to pneumomediastinum. On rare occasions, pneumomediastinum during asthma exacerbations can lead to life-threatening respiratory and hemodynamic compromise.^{50,50a} Although chest radiographs are not routinely obtained during attacks of asthma, pneumomediastinum was noted in 5.4% of 479 radiographs of children admitted with asthma attacks.⁵¹

Cigarette smoking has been implicated as a predisposing factor in spontaneous pneumomediastinum, although the mechanism is unclear.^{42,52}

Precipitating Factors. Voluntary manipulations of the breathing pattern can sometimes lead to alveolar rupture. "Voluntary pressure breathing," a practice originally proposed for fliers during World War II, consisted of slow, deep inhalations followed by forced exhalation through tightly pursed lips. This maneuver was also advocated by some mountain climbers as a means of getting more oxygen into the blood. However, this maneuver may lead to alveolar rupture. Patients with pneumomediastinum reported by Vosk and Houston⁵³ were members of the same climbing party who had both practiced "voluntary pressure breathing" during ascent.

Inhalational drug use is commonly cited as a precipitating factor in spontaneous pneumomediastinum.^{43,52} A typical example is pneumomediastinum after vigorous straining against a closed glottis during marijuana smoking⁵⁴ or after inhaling free-base cocaine,^{55,56} during which users sometimes add additional external airway pressure by having an accomplice blow vigorously into their mouths through a cardboard tube.⁵⁷ Of note, given the direct toxic effect of cocaine on lung parenchyma, some authors argue that pneumomediastinum following cocaine inhalation should be considered secondary.⁵² Recreational inhalation of nitrous oxide from disposable canisters was also reported as a cause of pneumomediastinum in two college fraternity brothers.⁵⁸

Involuntary manipulations of the breathing pattern are more common precipitating factors than voluntary maneuvers. Such causes of pneumomediastinum include straining or exertion such as during childbirth²; vomiting in association with bulimia,⁵⁹ hyperemesis gravidarum,⁶⁰ and diabetic ketoacidosis⁶¹; and prolonged straining during convulsive seizures,⁶² athletic competition,^{63,64} and violent coughing,⁶⁵ sneezing, hiccupping; and straining at stool.^{1,5} It is reasonable to expect that any activity producing large momentary swings in intrathoracic pressure could result in alveolar rupture leading to pneumomediastinum.

No Predisposing Condition or Precipitating Factor.

Although a history of a potential predisposing event or disease process is elicited in most patients with "spontaneous" pneumomediastinum, a few cases have been described without such associations and are known as *Hamman syndrome*. Hamman's original patient was a 51-year-old physician in whom no predisposing factor could be identified.³ Hamman later reported several additional cases of truly "idiopathic" pneumomediastinum; in modern series, cases have been reported despite normal lung parenchyma as determined by chest *computed tomography* (CT).^{3,66}

Secondary Pneumomediastinum

Mechanisms for secondary pneumomediastinum include blunt thoracic trauma, perforation of the esophagus or other viscus from invasive procedures, or unusual cases due to pathology in the neck, thorax, or abdomen,^{66a} as described previously.

Barotrauma. Barotrauma during mechanical ventilation accounts for up to one third or more of cases of secondary pneumomediastinum in recent studies.⁴² Alveolar rupture during positive-pressure ventilation is thought to result from overdistention in an area with abnormal airways or lung parenchyma. Subsequent dissection of air proximally toward the mediastinum results in pneumomediastinum, and rupture through the mediastinal pleura leads to the development of pneumothorax. Before the era of low tidal volume ventilation, barotrauma developed in almost a one fourth of mechanically ventilated patients and was associated with high mortality.²³ Historically, large delivered tidal volumes and high levels of positive end-expiratory pressure were thought to predispose mechanically ventilated patients to barotrauma, but these associations were likely related to the severity of the underlying lung disease.^{16,67,68} Gammon and others have shown the *acute*

respiratory distress syndrome (ARDS) was the condition most commonly associated with barotrauma and, among ventilated patients, was the only independently associated risk factor for barotrauma.^{23,69} Ventilator settings, including tidal volume, peak and plateau airway pressures, have not been found to be associated with barotrauma in a heterogeneous population of mechanically ventilated patients.⁷⁰ Although rates of barotrauma in low tidal volume (6 mL/kg) lung-protective ventilation strategies are reported to be the same as in traditional tidal volumes (12 mL/kg) in large clinical trials,⁶⁸ the overall rate of barotrauma appears to be lower when compared with historical references and clinician experiences.^{23,68}

Noninvasive forms of positive-pressure ventilation are less often associated with barotrauma than is conventional mechanical ventilation. This is probably because of the lower airway pressures used and the less severe lung diseases being treated. For instance, continuous positive airway pressure applied by mask was associated with pneumomediastinum in only 1 of 331 applications of this therapy, as cited in one review.⁷¹

Air or oxygen inadvertently insufflated under high pressure, as for example during manual ventilation during cardiopulmonary resuscitation, is especially likely to cause barotrauma. Improperly connected oxygen tubing preventing exhalation has resulted in life-threatening barotrauma,⁷² as have similar errors following anesthesia and surgery.^{73,74}

Deceleration injury, even when there is no open chest wound or displaced rib fracture, can cause barotrauma. Although such deceleration injuries most commonly result from motor vehicle accidents, they can also follow blows to the chest or falls into water with the glottis closed.^{14,75} Pneumomediastinum has also been caused by resuscitation using the Heimlich maneuver.⁷⁶

Infections. Infectious etiologies of secondary pneumomediastinum include mediastinitis with gas-forming organisms, *Pneumocystis jirovecii* pneumonia patients infected with human immunodeficiency virus (eFig. 84-7), or pneumonia with cavitary lesions.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms, Physical Signs, and Laboratory Findings

Chest pain is the most common symptom reported by patients with pneumomediastinum.^{1,66} It has been reported in the majority of patients with “spontaneous” pneumomediastinum and may account for some cases of unexplained acute chest pain in otherwise healthy young people.^{66,77} The pain is characteristically substernal in location and aggravated by movement, breathing, and position changes. It often radiates to the back, shoulder, or arm. Discomfort may extend into the neck, and retropharyngeal or perilaryngeal air dissection may give rise to dysphagia or dysphonia, with characteristic muffled voice. Dyspnea and cough are also common symptoms.⁶⁶ In half of the cases, physical examination reveals palpable crepitation in the neck and supraclavicular area,⁷⁷ and cyanosis and neck vein distention have also been observed.²¹ *Hamman sign*, or Hamman’s

crunch,^{21,78} is a crunching or clicking sound synchronous with the heartbeat, heard over the precordium, and increased in intensity during inspiration and in the left lateral decubitus position.^{1,21,79} It has been described as similar to the noise produced by rubbing two rubber balloons together.²¹ Although considered by Hamman to be pathognomonic for the presence of mediastinal air, it can occasionally be heard in other circumstances such as with pneumothorax without radiographic evidence for pneumomediastinum.¹

Low-grade fever, along with mild to moderate leukocytosis,^{1,21} likely results from reactive inflammation associated with air dissecting in the mediastinum. In one series, leukocyte counts were reported to be greater than 10,000/mm³ in 16 of 23 patients and greater than 20,000/mm³ in 5 of 23, returning to normal without treatment within 1 to 2 days.²¹

Electrocardiographic changes are seen in some cases of pneumomediastinum without evidence of other cardiac abnormalities.²¹ The electrocardiogram may show diffusely low voltage, nonspecific axis shifts, ST-T wave changes, and ST segment elevation in the lateral precordial leads.²¹ These changes are also observed in association with pneumothorax and may be in part related to physical displacement of mediastinal structures.

Radiographic Features

Pneumomediastinum is most often detected by chest radiography and the finding of pneumomediastinum may be the first manifestation of extra-alveolar air. The diagnosis is usually made by demonstrating a thin line of radiolucency, best seen along the left heart border (Fig. 84-4 and eFig. 84-8A; see eFig. 84-5A).¹ Other common signs are the highlighting of the aortic arch, which is surrounded by increased radiolucency, and the “continuous diaphragm”

Figure 84-4 Pneumomediastinum. Chest radiograph of a 47-year-old man in whom mediastinal emphysema developed while he was hospitalized for treatment of right lower lobe pneumonia; image shows displacement of the mediastinal pleura by air (arrows).

Figure 84-5 Pneumomediastinum. The “continuous diaphragm” sign in a patient with pneumomediastinum that developed during mechanical ventilation for acute respiratory distress syndrome. An unbroken radiolucent line (*large arrowheads*) is visible from one hemidiaphragm to the other, rendering the inferior heart border clearly visible. Air is also present in the mediastinum (*small arrowheads*) and in the soft tissues of the shoulders, neck, and chest wall.

sign,⁸⁰ an unbroken radiolucent line extending from one hemidiaphragm to the other beneath the heart (Fig. 84-5 and see eFig. 84-8B). Mediastinal air may be easier to see on films obtained with the patient in lateral projection, which may demonstrate retrosternal air or vertical lucent streaks outlining the aorta, pulmonary artery (the so-called ring-around-the-artery sign; see eFig. 84-8C and D), or other mediastinal structures.¹ Less commonly encountered chest radiographic findings of pneumomediastinum include the “extrapleural air” sign (see eFig. 84-8E and F), Nacle-rio’s “V” sign (see eFig. 84-8G), elevation of the residual thymus (typically in younger patients, referred to as the *thymic spinnaker-sail sign*; see eFig. 84-8H-J), and air or gas trapped within the pulmonary ligament (see eFig. 84-8K). Distinguishing between mediastinal emphysema and a small pneumothorax may be difficult. Film obtained with the patient in the lateral decubitus position may show air rising to the most elevated portion of the thorax if it is free to move in the pleural space, whereas mediastinal air moves little with changes in position.⁸¹ Other chest radiographic findings that may mimic the appearance of pneumomediastinum include an unusual appearance of the major (oblique) fissure (eFig. 84-9), medial bullae, and Mach bands (eFig. 84-10).

Subcutaneous emphysema is readily detected as streaks or pockets of air outlining the tissue planes in the neck or chest. It often outlines the tissue compartments of the chest wall, clearly identifying the pectoral muscles. Both subcutaneous emphysema and pneumomediastinum are common findings in patients on mechanical ventilators,^{82,83} being present in 7% of cases in one early series (Fig. 84-6).⁸² These signs of alveolar rupture during positive-pressure

Figure 84-6 Pneumomediastinum. CT of the chest shows pneumomediastinum associated with extensive subcutaneous emphysema in a patient undergoing mechanical ventilation for acute respiratory distress syndrome. Mediastinal air is seen in both the middle and the posterior mediastinal compartments.

ventilation are important clinical danger signals, because pneumothorax may develop in at least half of these patients.^{23,83}

Chest CT is more sensitive than chest radiographs for detecting aberrant air in all its forms and should be considered when important management decisions rest on a given distinction or when the underlying cause is not evident.⁸¹ This is especially true in patients with pneumomediastinum due to blunt trauma, in which only 15% could be detected by chest radiographs.⁸⁴

APPROACH TO MANAGEMENT

Natural History

In most cases of pneumomediastinum, air spreads throughout the mediastinum and vents out of the thorax into the subcutaneous tissue planes.¹ Subcutaneous emphysema can become massive and prove distressing to both patient and physician, but it is seldom dangerous. Subcutaneous air collections will resolve spontaneously without surgical decompression once the primary air leak has sealed. Complete resolution of subcutaneous emphysema usually requires a couple of weeks, and hence counseling patients who are clinically stable is an important component of its management.

Management of Spontaneous Pneumomediastinum

Treatment of predisposing or precipitating factors of spontaneous pneumomediastinum is usually followed by gradual resolution of the aberrant air. Supplemental oxygen may hasten reabsorption, but specific therapy for pneumomediastinum is rarely needed. Most cases resolve with conservative management alone.^{85,85a}

In rare instances pneumomediastinum can produce life-threatening cardiovascular collapse.^{2,5,86} An early, well-documented incident was described by Laënnec more than 150 years ago, as related by Munsell.²¹ The great French clinician was called to see a small boy who had been

run over by a dung cart: Laënnec describes how his 4-year-old patient was placed in a tent with a candle for light. With the boy in extremis, Laënnec inserted sharp sticks into the boy's neck, supraclavicular areas, and anterior portion of the chest; a rapid, large outpouring of air extinguished the candle and the boy recovered. Modern medicine can add little more to this emergency decompression regimen except for the substitution of needles for sticks.

Most experienced clinicians reserve invasive therapy for cases of increasing airway impingement or cardiovascular compromise (eFig. 84-11). In these instances, small infraclavicular venting incisions seem to be the most prudent initial approach.⁸⁷

Management of Pneumomediastinum During Positive-Pressure Ventilation

The appearance of mediastinal or subcutaneous air in a patient receiving positive-pressure ventilation should prompt an assessment of the patient's physiologic response as well as the ventilator status. Immediate discontinuation of positive-pressure ventilation is usually not feasible, but adjustments to the ventilator can diminish the tendency of air to enter the mediastinum and reduce the risk of developing pneumothorax. Delivered tidal volumes should be reduced if possible. Positive end-expiratory pressure should be reduced or discontinued. Occult positive end-expiratory pressure, or "auto-PEEP," can augment air leakage and, if present, should be reduced.⁸⁸ Finally, bronchospasm and other potentially reversible contributors to air trapping during mechanical ventilation should be treated. Cough suppression should be considered.

Tracheobronchial disruption causing extra-alveolar air requires prompt diagnosis and surgical repair.¹³ This condition should be considered in a patient with blunt thoracic trauma in the presence of extensive soft tissue emphysema, airway bleeding, or nonresolving pneumothorax (see eFig. 84-2).^{1,14} Tracheobronchial disruption is certain if, on chest radiography, the collapsed lung tissue appears to have fallen away from the hilum (see Fig. 76-10).⁸⁹ When these findings are present, the patient should be taken to the operating room, where the first step is emergent bronchoscopy to confirm the diagnosis.¹ Performing the bronchoscopy in the operating room allows for immediate surgical intervention once confirmed. An exception can be made in the scenario of a trauma patient who is intubated and clinically stable with a pneumomediastinum found on CT imaging that could represent either an artifact or a small tear in the tracheobronchial tree. In these stable patients, one can do a quick bedside bronchoscopy to confirm the diagnosis which, if confirmed, would necessitate immediate operating room availability. However, these are situations which must be closely coordinated with thoracic surgery to ensure there is no delay in intervention.

MEDIASTINITIS

The term *mediastinitis* encompasses a number of loosely related processes that induce inflammation of mediastinal structures. Most forms of mediastinitis are infectious, and variations in their clinical presentation depend largely on the chronicity of the underlying process rather than on the

specific microbial cause. *Acute* mediastinitis is usually dramatic in presentation and requires prompt recognition and treatment. *Chronic* mediastinitis encompasses a spectrum that ranges from active granulomatous infection to end-stage fibrosis. The paucity of recent literature on these subjects reflects the relative rarity of mediastinitis. Nonetheless, recognition of mediastinitis and its forms is important because of its devastating morbidity and mortality.

ACUTE MEDIASTINITIS

Acute mediastinitis was once a rare and usually fatal condition seen after rupture of the esophagus from forceful vomiting (see eFig. 84-11) or in conjunction with penetrating trauma. With the advent of endoscopic procedures and cardiac surgery via median sternotomy, acute mediastinitis is now most commonly encountered as an iatrogenic complication and may vary in clinical presentation. Relatively indolent infections may be termed "suppurative" rather than "acute." In either case, a distinction is drawn between these disorders and chronic "granulomatous" and "fibrosing" mediastinitis.

The following discussion characterizes the clinical picture and management of acute mediastinitis according to the mechanism of access to the mediastinum (Table 84-3).

Mediastinitis Resulting from Visceral Perforation

Boerhaave syndrome refers to esophageal rupture associated with forceful vomiting (see eFigs. 84-5 and 84-11), classically after overeating or excessive drinking. It is the most familiar example of acute mediastinitis,^{90,91} although no longer the most common. Unilateral or bilateral hydro-pneumothorax is common and quickly progresses to empyema (Fig. 84-7). Spontaneous esophageal rupture can be difficult to diagnose and may be mistaken for an abdominal catastrophe especially in the patient who may not be

Table 84-3 Acute Mediastinitis: Etiologies and Clinical Settings

PERFORATION OF A THORACIC VISCUS

Esophagus

Forceful vomiting (Boerhaave syndrome)

MEDIASTINITIS AFTER CARDIOTHORACIC SURGERY

INHALATIONAL ANTHRAX

Figure 84-7 Esophageal perforation. Chest radiograph of a 64-year-old woman 16 hours after traumatic perforation of the esophagus showing a subtle lucency along the lateral aortic arch (arrowheads) representing pneumomediastinum. In addition, left-sided pneumothorax (arrows) and pleural effusion are evident."

able to relate a clear history. During a violent vomiting episode, the pressure in the esophagus can increase to the point at which it overcomes the tensile strength of the normal esophageal wall. The most common location of perforation is the lower left posterolateral wall, where the muscle bundles in the longitudinal layer of the esophagus can separate, allowing a bubble of mucosa to protrude into the mediastinum and burst.

In the classic description of acute mediastinitis related to esophageal rupture, the onset is sudden and dramatic. Patients complain of severe, unrelenting substernal chest pain which is worsened by breathing or coughing, and may report a sense of impending doom. The pain may be referred into the neck and ear if there is involvement of the superior mediastinum. Radicular pain that radiates around the chest and between the scapulae suggests involvement of the posterior or inferior mediastinum. Symptoms and signs of systemic toxicity—high fevers, chills, tachycardia, and tachypnea—are prominent. Examination may reveal supraclavicular fullness, tenderness over the sternum or sternoclavicular joints, crepitus, and other signs of mediastinal and subcutaneous emphysema. Hamman sign is characteristic but not always present. Tracheal deviation, jugular venous distention, and other signs of compression of mediastinal structures may appear later in the clinical course. These features are typical after spontaneous esophageal rupture as seen in Boerhaave syndrome, but may not be present in less acute settings.

While still rare, esophageal perforation during diagnostic or therapeutic endoscopic procedures is an important cause of acute mediastinitis in the contemporary era.⁹² Diagnostic upper endoscopy causes a perforation at a rate of less than 0.03%.⁹³ Therapeutic maneuvers, such as dilation of strictures (eFig. 84-12) and endoscopic mucosal resection, have a much higher risk of perforation, from 2% to 6%.⁹³ Additionally, therapy of malignant lesions is more likely to be complicated by perforation than that of benign lesions.⁹⁴

The esophageal obturator airway and swallowed foreign bodies can also perforate the esophagus, particularly if their

use is intended to induce injury. One series describes six prison inmates who swallowed hypodermic needles fashioned in the shape of "stars" to win temporary reprieves from incarceration.⁹⁵ All required surgical management. Accidental or intentional ingestion of caustic solutions such as paraquat or lye also can lead to esophageal perforation.²⁷

The diagnosis of esophageal perforation depends on an appropriate degree of clinical suspicion. On chest radiograph, the hallmarks are diffuse mediastinal widening and the presence of air in the mediastinum and adjacent soft tissues. Mediastinal air-fluid levels may be seen, and pneumothorax or hydropneumothorax may be present. CT can delineate these abnormalities more clearly. Passage of ingested contrast material into the periesophageal or pleural space may be observed.^{96,97}

Frank uncontained esophageal perforation requires prompt surgical repair, drainage of the mediastinum and often the pleural spaces, and administration of appropriate antibiotics.^{98,99} Percutaneous catheter drainage of mediastinal abscesses, under CT guidance, has been used when the infection is localized and the clinical setting is less urgent (see eFig. 84-12E-H). In a series describing 51 patients 3 died before intervention could be accomplished, 31 underwent standard thoracotomy and repair leading to 11 deaths, and 17 highly selected patients with minimal contamination were managed successfully with targeted drainage and antibiotic therapy.¹⁰⁰

If esophageal perforation due to endoscopy is detected early, morbidity and mortality can be avoided with prompt treatment. Clips may be used to repair small perforations endoscopically if detected immediately. In selected cases, esophageal perforation can be contained using endoscopically placed stents.^{101,102} In addition, a surgeon should be involved as soon as a perforation is detected and broad-spectrum antibiotics should be administered.⁹³ The rate of recovery is high when perforations are repaired within 24 hours.

Complications of acute mediastinitis after esophageal rupture may include localized abscess formation, extensive pleural empyema, and persistent esophagocutaneous fistulas. A prolonged course is usual, and reexploration may be necessary to ensure adequate drainage. Reported mortality has varied due to differences in patient selection and management approaches. Timing of surgical drainage has been of prime importance in determining the clinical outcome. Modern series reporting the use of consistently aggressive surgical management cite up to 90% survival after spontaneous esophageal rupture.^{103,104}

Bronchoscopic airway perforation and migration of indwelling central venous catheters are other iatrogenic causes of mediastinitis. Bronchoscopy is a much less frequently reported cause of mediastinitis than esophagoscopy.¹⁰⁵ However, increasing use of laser and mechanical endobronchial procedures, often performed in the setting of malignancy, with chronic airway colonization or postobstructive pneumonia, add to the likelihood of potential mediastinal complications. Mediastinitis has been reported after endobronchial ultrasound-guided transbronchial needle aspiration, but is overall a rare event.¹⁰⁵ Intravascular catheters may be another source of acute mediastinitis when the catheter tip erodes through the vessel wall into

Figure 84-8 Venous perforation of a peripherally inserted venous catheter with entry into the mediastinum. Axial (A–E; see [Video 84-2](#)) and sagittal (F–H) enhanced chest CT show a left upper extremity peripherally inserted venous catheter (arrowheads) coursing through the left subclavian and brachiocephalic veins (arrowheads, A–C), but then coursing caudally into the anterior mediastinum (arrowheads, D and E). A mediastinal gas collection (arrows) represents a developing abscess. (Courtesy Michael Gotway, MD.)

the mediastinum ([Fig. 84-8](#) and [Video 84-2](#)). Instillation of hyperosmotic,¹⁰⁶ vesicant, or vasoactive substances via these catheters may induce a chemical, rather than an infectious, inflammation.

Direct Extension of Infection from Extramediastinal Sites

Descending necrotizing mediastinitis is infection that has extended directly into the mediastinum from a head and neck source.¹⁰⁷ Periodontal, peritonsillar, odontogenic, or pharyngeal infection may extend to the mediastinum via the prevertebral, visceral, or pretracheal spaces or carotid sheaths,^{6,108} although the usual route is via the retropharyngeal space to the posterior mediastinum ([Fig. 84-9](#)).^{109,110} Recent studies demonstrate a shift from odontogenic infection to pharyngeal infection as the most common source of descending necrotizing mediastinitis.^{107,111,112} Most infections are mixed, with both aerobic and anaerobic organisms; purulent pleural and pericardial involvement is common.¹⁰⁷ Mediastinal infection of this type rapidly leads to sepsis and multiorgan failure and carries a high mortality rate.^{109,110,113,114} High preoperative mortality is most strongly related to a delay in diagnosis.¹¹⁵

In addition to the clinical signs described previously for acute mediastinitis after esophageal perforation, patients with descending necrotizing mediastinitis may have widening of the retropharyngeal space, with or without associated air-fluid levels, anterior displacement of the tracheal air column, and loss of the normal cervical spine lordosis on lateral films of the neck. CT of the neck and chest are usually definitive ([Fig. 84-10](#)).¹⁰⁹

Successful treatment of descending necrotizing mediastinitis depends on early recognition and diagnosis, prompt antibiotic administration, and timely and aggressive surgical drainage. Multiple surgical approaches are available for mediastinal drainage and the choice of procedure depends

Figure 84-9 The three deep spaces of the neck and their communication with the mediastinum. (Redrawn from Freeman RK, Vallières E, Verrier ED, et al: Descending necrotizing mediastinitis: an analysis of the effects of serial surgical debridement on patient mortality. *J Thorac Cardiovasc Surg* 119:260–267, 2000.)

Figure 84-10 Chest CT of a 35-year-old man with descending necrotizing mediastinitis. **A**, At the level of the hyoid bone in the neck, there is gas in the retropharyngeal soft tissues (arrow) with parapharyngeal space inflammatory stranding. **B**, At the level of the aortic arch in the chest, there is gas outlining the great vessels (arrows). There are inflammatory changes in the paratracheal tissues, and bilateral pleural effusions (**E**). (From Corsten MJ, Shamji FM, Odell PF, et al: Optimal treatment of descending necrotizing mediastinitis. *Thorax* 52:702–708, 1997.)

on the extent of involvement and the patient's condition.¹¹⁵ A cervical approach is used for drainage of disease localized in the upper mediastinum, although most surgeons now advocate for transthoracic exploration and debridement if there is any suspicion of diffuse disease.^{107,112} This more aggressive approach is supported by findings of Corsten and coworkers¹⁰⁹ that the mortality rate of patients treated with cervical drainage alone was 47% compared with 19% when thoracic mediastinal drainage was added. Routine serial postoperative cervicothoracic CT imaging and aggressive reexploration and drainage guided by these imaging findings appear to reduce the mortality of this condition even further.¹¹⁰ In a recent series of 17 patients, in whom transthoracic surgery was performed within a median time frame of 6 hours after radiographic diagnosis, only one patient experienced an early death.¹¹⁴

Although video-assisted thoracic surgery and other percutaneous drainage procedures have been described and may be appropriate in early-stage disease, open surgical drainage and irrigation remains the standard approach. Direct extension of infection from elsewhere in the chest is a rare cause of acute mediastinitis. Such extension can be associated with eroding neoplasms, with anterior chest wall and neck infections in injection drug users, or as a compli-

cation of vertebral or costal tuberculous infection. Penetrating chest injuries may result in acute mediastinitis, especially if the wound causes visceral perforation or is grossly contaminated, or if there has been a delay in reaching medical attention. In such instances, the diagnosis of acute mediastinitis may not be apparent if the patient has other serious injuries.

Pancreatitis has been reported to extend into the mediastinum, presenting as mediastinal widening with the clinical picture of acute mediastinitis. Spread in such a circumstance is presumably via the aortic and esophageal hiatuses. Both gastric and esophageal ulcers have been reported as causes of mediastinitis, sometimes eroding into the pericardium.

Mediastinitis After Cardiothoracic Surgery

Mediastinitis after cardiac surgery^{116,117} and after heart and heart-lung transplantation is another significant form of acute mediastinitis of iatrogenic etiology in the modern era.¹¹⁸⁻¹²⁰

The incidence of mediastinal infection after cardiac surgery has been variously reported at 0.4% to 5.0% but, in a more recent series, the reported rate was less than 1%.¹²¹ Post-sternotomy mediastinitis has become a substantial clinical problem, not because of a high case incidence but rather because cardiac surgery via median sternotomy has become such a widely used procedure.

Risk factors that appear to predispose to development of mediastinitis after cardiac surgery include underlying comorbidities such as diabetes mellitus and obstructive lung disease, as well as advanced age.^{121,122,122a} Perioperative risk factors include shaving rather than clipping for hair removal, the use of bilateral internal mammary artery grafts, a longer duration of the surgical procedure and perfusion time, greater use of cautery or bone wax, low cardiac output state in the early postoperative period, and greater amounts of postoperative bleeding. The incidence of postoperative mediastinitis appears to be increased further if reoperation is required to control bleeding, if multiple valve replacement accompanies coronary artery bypass, or if the patient requires more than 48 hours of mechanical ventilation postoperatively.

Careful infection control measures and scrupulous aseptic technique in the operating room remain important means of prevention.¹²¹ The prophylactic intranasal application of mupirocin ointment has been shown to reduce by 50% the rate of *Staphylococcus aureus* nosocomial infections in carriers who undergo major surgery,¹²³ leading to the suggestion that it be used routinely.

The bacteriology of postoperative mediastinitis parallels that of early prosthetic valve endocarditis. *Staphylococcus epidermidis* and *S. aureus* have been the most frequent isolates in several series,^{124,125} and as many as 40% of cases have mixed infections.¹²⁴ Methicillin-resistant *Staphylococcus aureus* is a relatively uncommon but virulent cause.¹²⁶ Rare organisms include anaerobes and gram-negative bacilli,^{124,127} *Candida* species,^{124,128} and nontuberculous mycobacteria (especially *Mycobacterium chelonae* and *Mycobacterium fortuitum*).¹¹⁶

Acute mediastinitis presenting after cardiac surgery tends to be less devastating than that seen in the settings described previously, perhaps because it remains relatively

localized longer and tends to be recognized earlier. Typically, the clinical course consists of fever and systemic signs, followed by bacteremia and local signs of wound infection.¹²⁹ Drainage from the sternotomy incision and other localizing findings are present in the great majority of patients.^{124,129,130}

The diagnosis is usually made at the time of reexploration of the sternotomy wound and rests on a high clinical suspicion in the appropriate setting. CT is particularly helpful in identifying and discerning soft tissue swelling, fluid collections, and sternal erosion or dehiscence (eFig. 84-13).¹³¹ However, because swelling and fluid collections are common in the early postoperative period, their significance is much more clear when they persist or develop after 14 days.^{131,132} Patients with fever, positive blood cultures, and wound abnormalities in the post-sternotomy period should be evaluated surgically. As in other settings, therapy for post-sternotomy mediastinitis consists of administration of systemic antibiotics and early surgical exploration with débridement and drainage.^{121,124,133,134} Reported mortality from mediastinitis after cardiac surgery varies considerably. These patients typically require multiple surgical procedures and eventual coverage of the wounds with vascularized muscle flaps. Currently, most patients survive, with mortality rates of 20% to 40%.^{121,129} Hospitalization of survivors is usually prolonged by this complication.¹³⁵

“Primary Mediastinitis”: Inhalational Anthrax

Anthrax, caused by infection with *Bacillus anthracis*, is primarily a disease of cattle, sheep, and goats and is most prevalent in the Middle East, although it is now recognized as an important disease of bioterrorism (see Chapter 40). Clinical syndromes are classified by primary site of infection: cutaneous, gastrointestinal, injectional, or inhalational. The most common form of anthrax, the cutaneous form, is contracted by direct inoculation usually from handling hides or hair from infected animals. Gastrointestinal anthrax is due to ingestion of meat contaminated with anthrax spores. Recently, injectional anthrax has emerged as a severe soft tissue infection seen in heroin users in the United Kingdom and Europe.¹³⁶

Inhalational anthrax, or *wool sorter's disease*, is contracted by inhaling *B. anthracis* spores from animal sources. Anthrax spores inhaled into the distal air spaces are ingested by alveolar macrophages and transported to the mediastinal lymph nodes, where they induce a hemorrhagic mediastinitis, followed by bacteremia, overwhelming sepsis, and shock. Mortality is high, even with aggressive supportive care.¹³⁷⁻¹³⁹ Virulence of the anthrax bacillus is related to the production of two toxins, called *lethal* and *edema* toxins, as well as a capsule that resists phagocytosis.¹³⁶ Sporadic anthrax is fortunately rare, with one report documenting only two confirmed cases in this country in 25 years.¹⁴⁰ However, anthrax has remained a very real concern because of its devastating clinical effects and its ominous potential as an agent of biologic warfare and bioterrorism.^{138,139,141,142} In 1979, there was an outbreak of 42 cases after the accidental release of weapons-grade anthrax in Sverdlovsk, Russia.¹⁴¹ In the fall of 2001, this potential was realized when *B. anthracis* spores were intentionally dispersed through the U.S. Postal Service system, resulting in an outbreak of 11 cases of cutaneous anthrax and 11 cases of inhalational anthrax.^{143,144}

Modern clinical knowledge of inhalational anthrax has been largely derived from these limited outbreaks. Patients typically experience a biphasic illness with an initial flulike illness lasting 2 to 4 days and characterized by fever, malaise, myalgias, and nonproductive cough. This is followed by a fulminant phase of acute mediastinitis, with respiratory distress, chest pain, cyanosis, and hemodynamic instability.^{138,139,143,144} Once septic shock has developed, it is usually resistant to aggressive supportive measures.¹³⁶ The chest radiograph and chest CT typically show mediastinal widening and pleural effusions (see Fig. 40-2).¹⁴⁵ A triad of hemoconcentration, widened mediastinum, and altered mental status are characteristic of inhalational anthrax and help distinguish it clinically from community-acquired pneumonia.¹³⁶ The diagnosis is established by demonstration of gram-positive, boxcar-shaped bacilli in tissue or body fluid specimens or in the blood buffy coat. A direct fluorescent antibody test, polymerase chain reaction, and serologic tests are available for confirmation.

Historically, inhalational anthrax has been a devastating disease even with appropriate treatment: 12 of 13 well-documented sporadic cases in the United States had fatal outcomes.¹³⁷ In the 2001 bioterrorism outbreak, prompt diagnosis and initiation of antibiotic therapy plus aggressive drainage of mediastinal and pleural collections resulted in the survival of 6 of the 11 patients.¹⁴⁴

The cornerstone of treatment is prompt antibiotic administration upon first suspicion of anthrax. Recommended initial treatment options include ciprofloxacin or doxycycline with a second agent, either clindamycin or penicillin.¹³⁶ Anthrax is resistant to third- and fourth-generation cephalosporins. Most patients in the bioterrorism outbreak were treated with multiple agents including a fluoroquinolone.¹⁴³ For postexposure prophylaxis, ciprofloxacin or doxycycline orally as well as immunization with antitoxin antibodies is recommended.^{136,146}

CHRONIC GRANULOMATOUS MEDIASTITIS AND MEDIASTINAL FIBROSIS

Chronic granulomatous mediastinitis and mediastinal fibrosis are two manifestations of chronic mediastinal disease. Disorders falling along the continuum from active granulomatous mediastinitis to pure mediastinal fibrosis have been identified by a variety of terms in the literature—mediastinal adenitis, mediastinal granulomatosis, sclerosing mediastinitis, mediastinal collagenosis, fibrosing mediastinitis, and idiopathic fibroinflammatory lesion of the mediastinum—but conceptually, all these entities may be thought of as variations of a common process (Fig. 84-11).

Etiologies and Pathophysiology

In North America, the majority of cases of granulomatous mediastinitis are caused by histoplasmosis; worldwide, tuberculosis is the most common etiology.¹⁴⁷⁻¹⁵⁰ Histoplasmosis and tuberculosis together account for 83% of the confirmed diagnoses.^{147,151} Granulomatous infection is the usual cause of mediastinal fibrosis (see Fig. 84-11).

The most important noninfectious etiology of chronic mediastinal disease is sarcoidosis, which accounts for 11% of the cases of granulomatous mediastinitis of known

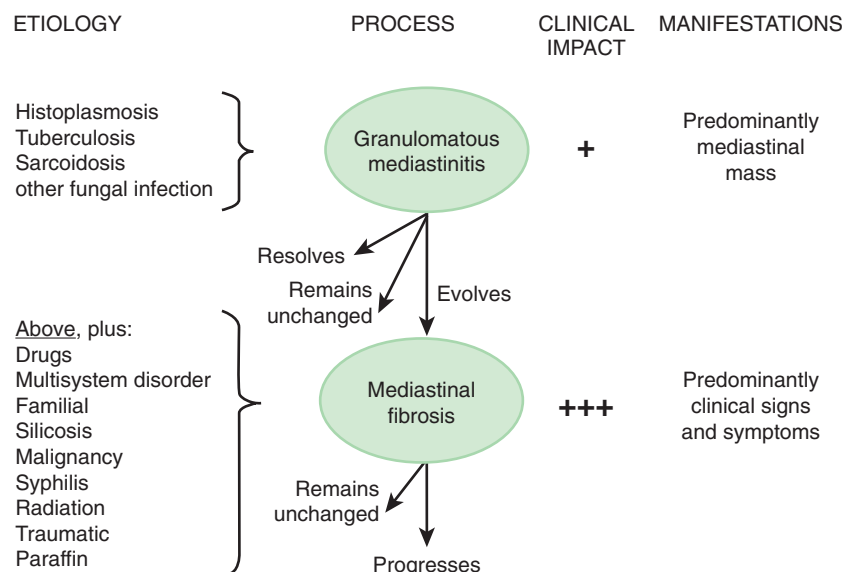

Figure 84-11 Pathophysiologic relationships between granulomatous mediastinitis and mediastinal fibrosis.

cause.¹⁴⁷ Methysergide, a drug once used in the control of severe vascular headache, is well-known for causing mediastinal fibrosis. Other reported noninfectious causes of mediastinal fibrosis include silicosis,¹⁵² paraffin (as a late complication of plumbage for tuberculosis), and traumatic mediastinal hematoma.¹⁵³ Nodular sclerosing Hodgkin lymphoma may also masquerade as mediastinal fibrosis.¹⁵⁴ Mediastinal irradiation has been reported to cause mediastinal fibrosis with superior vena caval and bronchial obstruction.¹⁵⁵

The genesis of chronic mediastinal disease is most easily understood using histoplasmosis or tuberculosis as an example. Infection begins as a primary focus in the lung, which spreads to mediastinal lymph nodes and induces mediastinal adenitis and periadenitis. Eventually, a cluster of caseating lymph nodes breaks down into an irregular mass, heals by fibrous encapsulation and, in some cases, undergoes dense calcification. The thickness of the fibrotic capsule is the main determinant of the clinical picture: when 2- to 5-mm in thickness, it has little clinical impact, whereas, if the capsule reaches 6 to 9 mm, it can invade or interfere with adjacent tissues.^{148,156} This benign localized “healing” process produces physiologically important effects because of the compact nature of the mediastinum and the importance and vulnerability of its structures (Fig. 84-12). Whether either of these concepts or some other mechanism is responsible, it is evident that the host response plays an important role.

The symptoms and physiologic effects of this process are determined by the location of the involved lymph nodes. Most commonly, the involved lymph nodes are in the right perihilar region (eFig. 84-14); perhaps this predilection for a right-sided location accounts for the high prevalence of superior vena cava (SVC) obstruction in chronic mediastinitis. Later, in instances in which the process progresses to generalized fibrosis, the entire upper portion of the mediastinum may be involved.

Clinical Manifestations

On the continuum from active granulomatous mediastinitis to mediastinal fibrosis, the former tends to be asymptomatic

Figure 84-12 Mediastinal fibrosis. Axial CT through the main pulmonary artery shows abnormal soft tissue infiltrating the mediastinum (arrows), compressing the main pulmonary artery (arrowheads). The presence of mass effect on vessels and bronchi is characteristic of mediastinal fibrosis.

and to be discovered incidentally by chest radiography; the latter tends to cause clinical manifestations.⁷⁸ In 52 patients with mediastinal fibrosis and evidence of histoplasmosis reviewed by Loyd and associates,¹⁵⁷ initial symptoms included cough in 41%, dyspnea in 32%, hemoptysis in 31%, and chest pain in 23%. Clinical manifestations develop either because the fibrotic process invades or compresses mediastinal structures or because a calcified mass erodes into adjacent structures. These manifestations can be grouped into those related to involvement of the SVC, the airways, the esophagus, the major pulmonary vessels, and mediastinal nerves.

Superior Vena Cava Obstruction. SVC obstruction has been the most frequent complication of granulomatous mediastinitis and mediastinal fibrosis in some series.^{147,158} Although most patients with SVC obstruction have malignancy (see eFigs. 83-1 and 83-2), benign causes account for about 3% to 6% of large published series,^{159,160} of which

Figure 84-13 Mediastinal fibrosis (in this instance from histoplasmosis) with superior vena cava obstruction and extensive collateral circulation. **A**, Frontal chest radiograph shows smooth widening of the superior mediastinum with a peripheral granuloma in the right lung (arrow). **B**, Imaging following rapid injection of contrast material into an antecubital vein shows complete obstruction of the superior vena cava (thick arrow), with filling of the internal mammary veins bilaterally (thin arrows). (From Fraser RG, Paré JAP, Paré PD, et al: *Diagnosis of diseases of the chest*, vol II, ed 3. Philadelphia, 1989, WB Saunders, p. 955.)

most are due to granulomatous mediastinitis or mediastinal fibrosis.¹⁵⁵ SVC obstruction can develop at any stage of granulomatous or fibrotic involvement; in Schowengerdt and coworkers' series,¹⁴⁷ SVC obstruction was present in 77% of symptomatic patients with granulomatous mediastinitis and in 52% of symptomatic patients with mediastinal fibrosis.

The typical presentation is SVC syndrome.¹⁶¹ Because obstruction develops gradually, collateral channels tend to divert much of the venous flow (Fig. 84-13). Therefore, symptoms may be less prominent than might be expected and may improve with time.¹⁵⁰ However, even chronic SVC obstruction can cause serious complications such as hemorrhage from esophageal varices, recurrent upper extremity thrombophlebitis, and postphlebotic syndrome. Less commonly, the inferior vena cava or azygos vein can be involved.¹⁴⁷ Thoracic duct obstruction is rare¹⁴⁷ but can produce chylothorax and its associated clinical manifestations.

Airway Involvement. Airway complications including dyspnea, cough, and hemoptysis were the most common clinical manifestations of chronic mediastinal disease in several series^{78,157} and constituted the most common indication for surgical intervention.⁷⁸ Any of the main airways may be compromised, but involvement of the right middle lobe is reported as most frequent and is often accompanied by features of the right middle lobe syndrome. A rare complication, bronchoesophageal fistula, may be heralded by simultaneous hemoptysis and hematemesis.¹⁶²

Esophageal Involvement. Esophageal involvement can include extrinsic compression, traction diverticula, disturbances of esophageal motility, or bleeding. Symptoms of dysphagia, chest pain, and eructation can result.¹⁴⁷

Pulmonary Vascular Involvement. Mediastinal fibrosis can involve major vessels on either side of the heart¹⁴⁷⁻¹⁴⁹ and, if so, the prognosis can be serious. Progressive obstruction of one or both main pulmonary arteries can result in pulmonary hypertension, cor pulmonale, and refractory right-sided heart failure (see eFigs. 37-1 and 54-22).¹⁶³

Stenosis of proximal pulmonary veins can cause a clinical picture similar to that of severe valvular mitral stenosis, with pulmonary venous hypertension and recurrent episodes of hemoptysis. Pulmonary venous hypertension can be unilateral when the veins from only one lung are involved and, thus, may result in unilateral pulmonary edema and fibrosis (see eFig. 37-1). Occasionally fibrotic changes involving the pulmonary parenchyma may be the result of previous pulmonary infarction when significant vascular compression is present (see eFig. 54-22). With flow-limiting systemic venous stenoses, collateral vessels are frequently abundant (see eFig. 54-21).

Mediastinal Nerve Involvement. Entrapment or compression of the mediastinal nerves can cause a variety of disorders. Hoarseness can result from involvement of the recurrent laryngeal nerve,^{147,149} diaphragmatic paralysis from involvement of one or both phrenic nerves, Horner syndrome from impingement on autonomic ganglions or nerves, and persistent tachycardia from damage to the vagus nerve.

Diagnosis and Management

In most instances, surgical exploration is necessary to distinguish between benign and malignant causes of SVC syndrome, localized mediastinal mass, or other manifestations of chronic mediastinitis. Occasionally, prior radiographs documenting an unchanged appearance or dense calcification within the mass permits a confident diagnosis without surgery.

Chest radiographs are abnormal in most patients. Granulomatous mediastinitis more often presents as a localized mass, usually in the right paratracheal area, and the later fibrotic state more frequently produces generalized widening of the superior portion of the mediastinum, but these characteristics vary.^{149,150} Mass lesions tend to be smooth and lobulated,¹⁵⁰ and contrast studies in cases of SVC obstruction typically show the affected area to be smooth and tapered,¹⁴⁹ in contrast to the more ragged appearances usually seen with cancer. In some cases, the mediastinum is normal in appearance on standard chest radiographs, and venography or chest CT is necessary to demonstrate the

anatomic basis of a clinically evident obstruction (see eFigs. 54-21 and 54-22).¹⁵⁰ Magnetic resonance imaging may be useful in assessing vascular compromise beyond what is shown on CT scan.¹⁶⁴

The role of specific medical therapy for granulomatous mediastinitis or mediastinal fibrosis is unclear.⁷⁸ Some evidence suggests that selected cases with active inflammation associated with histoplasmosis may benefit from antifungal therapy,^{158,165} but specific indications, if any, for antifungal therapy remain unknown. A similarly conservative approach should be taken to tuberculosis-related mediastinal complications, unless sputum or tissue samples are positive for mycobacteria or convincing clinical evidence of active tuberculosis is present.

The clinical manifestations of this disease appear to be the result of host factors as much as the infection itself. Accordingly, therapy has also been directed at the host inflammatory response. Anecdotal reports of treatment of mediastinal and retroperitoneal fibrosis with corticosteroids have reached opposite conclusions.^{166,167} It appears that diffuse forms of fibrosis may be more likely to respond to anti-inflammatory therapy.¹⁶⁸ As in the case of antimicrobial therapy, the appropriate role for anti-inflammatory therapy for granulomatous mediastinitis and mediastinal fibrosis is at present unknown.¹⁶⁹

At the time of exploration for diagnosis, some surgeons advise removal of as much of the inflammatory or fibrous mass as possible in order to reduce its bulk and perhaps diminish its later impact on adjacent tissues.¹⁶⁹ Surgical debulking is tedious and associated with significant morbidity and mortality. However, there have been anecdotal case reports of surgical intervention being successful in these patients.⁷⁸ Surgery to bypass an obstructed vena cava is technically difficult and not always effective, although this may still be considered in the setting of bleeding esophageal varices or recurrent upper extremity thrombophlebitis. Endovascular stent placement is another option (see eFig. 54-21).¹⁷⁰ Obstruction of major pulmonary vessels is a poor prognostic sign and, for this complication, therapeutic options are limited, with surgical reconstruction, angiographic dilation, and stent placement only rarely being successful.¹⁷¹

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of David J. Pierson, MD, who wrote this chapter for the first and second editions, and coauthored this chapter with DRP for the third edition. These earlier chapters contain more extensive historical references.

Key Points

- Pneumomediastinum refers to the presence of air or other gas in the mediastinum, which usually originates from alveolar rupture in the lungs but may arise from the upper respiratory tract or the gastrointestinal tract.
- Treatment of pneumomediastinum depends primarily on successful management of the underlying disease process. Rarely, direct intervention is needed to decompress air in the mediastinum.
- Acute mediastinitis is usually a sudden and severe disease that is now most commonly caused by perforation of the esophagus during endoscopic procedures and infectious complications after surgical procedures with sternotomy incisions.
- All forms of acute mediastinitis are life-threatening and require prompt diagnosis, imaging, surgical drainage, and antimicrobial treatment.
- Chronic mediastinitis results from granulomatous inflammation of the mediastinum, most commonly due to histoplasmosis and its fibrotic sequelae. Complications include bronchial obstruction, superior vena cava syndrome, esophageal compression, and pulmonary vessel obstruction.
- Management of chronic mediastinitis is aimed at relief of these mechanical complications. The role of anti-inflammatory and antimicrobial therapy is at present unclear.

Subcutaneous emphysema and pneumomediastinum are present. **B** and **C**, Axial chest CT displayed in lung windows performed at the level of the aortic arch shows focal dilation of the trachea (arrow, **B**), with the endotracheal tube exiting the right posterolateral trachea at the site of tracheal perforation (arrowhead, **C**). Pneumomediastinum (*) and subcutaneous emphysema are present. (Courtesy Michael Gotway, MD.)

eFigure 84-2 Left main-stem bronchial fracture following motor vehicle collision. **A**, Frontal chest radiograph shows subcutaneous emphysema with pneumomediastinum with a right apical pneumothorax (arrow) and a “deep sulcus” sign, also on the right. A left pneumothorax has been addressed with a left thoracostomy tube, although clinically a persistent air leak from this tube was present. **B** and **C**, Axial (see [Video 76-3](#)) and coronal (see [Video 84-1](#)) chest CT displayed in lung windows shows subcutaneous emphysema with pneumomediastinum (*) with a complete fracture of the left mainstem bronchus (arrows). A residual left apical pneumothorax (arrowhead in **B**) remains. (Courtesy Michael Gotway, MD.)

Figure 84-3 Pulmonary interstitial emphysema: chest CT appearance. A–C, Axial chest CT displayed in lung windows shows gas collections (*arrowheads*) surrounding the right lower lobe segmental and subsegmental arteries and airways, creating the appearance of a lucent “halo” around these structures, representing pulmonary interstitial emphysema. The pulmonary interstitial emphysema in this patient was spontaneous, although associated with an undiagnosed interstitial lung process, and was presumed to reflect peripheral alveolar rupture. (Courtesy Michael Gotway, MD.)

Figure 84-4 Pneumomediastinum resulting from a subdiaphragmatic source—perforated diverticulitis. A, Frontal chest radiograph shows free intraperitoneal gas outlining the right diaphragm (*arrowheads*), as well as extraluminal gas in the left upper quadrant (*). Left upper quadrant subcutaneous emphysema is also present. Axial CT performed through the thorax (B–D) and abdomen and pelvis (E–G) shows pneumomediastinum (*) extending from pneumoretroperitoneum (outlining the left kidney [K], in panel E, and arrowheads, E–G) resulting from perforated diverticulitis involving the descending colon (C, in panels F and G). (Courtesy Michael Gotway, MD.)

Figure 84-5 Esophageal rupture (Boerhaave syndrome): imaging findings. **A**, Frontal chest radiograph in a patient with chest pain shows pneumomediastinum, evidenced by elevation of the left mediastinal pleura, producing a gas lucency between the left heart border and medial left lung (*arrows*). Axial chest CT initially performed following intravenous contrast, prior to oral contrast administration (**B** and **C**), and after administration of oral contrast (**D** and **E**) shows pneumomediastinum (*arrows*, **B** and **C**) in close proximity to the esophagus (*arrowhead*, **C**). Left pleural effusion (*) is evident. Following administration of oral contrast (**D** and **E**), the contrast material can be seen to distend the esophagus (*arrowhead*, **D**) subsequently opacifying the areas of pneumomediastinum (*arrows*, **D** and **E**) extending toward the left pleural space, confirming an esophageal source for the perforation. (Courtesy Michael Gotway, MD.)

Figure 84-6 Spontaneous pneumomediastinum in a patient with interstitial lung disease. **A–D**, Axial chest CT displayed in lung windows shows extensive pneumomediastinum (*arrowheads*) and subcutaneous emphysema (*). Patchy bilateral basal predominant reticulation and architectural distortion represent fibrotic lung disease, with areas of more upper lobe predominant ground-glass opacity shown to reflect diffuse alveolar damage at surgical lung biopsy performed subsequently. The diffuse alveolar damage developed acutely, superimposed on the chronic fibrotic lung disease. (Courtesy Michael Gotway, MD.)

eFigure 84-7 Pneumomediastinum in a patient with AIDS and *Pneumocystis jirovecii* pneumonia. A–D, Axial chest CT shows diffuse ground-glass opacity associated with thin-walled cysts (arrows), representing pneumatoceles in the setting of *Pneumocystis jirovecii* pneumonia. Extensive pneumomediastinum (*) is present. Pneumomediastinum outlining the right upper lobe pulmonary artery (arrowhead, B) and interstitial emphysema, anterior to the left mainstem bronchus (arrowhead, C) are seen.
